

Concepts Are Not a Natural Kind*

Edouard Machery^{†‡}

In cognitive psychology, concepts are those bodies of knowledge that are stored in long-term memory and are used by default in human beings' higher cognitive processes (categorization, inductive and deductive reasoning, etc.). Most psychologists of concepts assume that these mental representations share many scientifically important properties, and the psychology of concepts is expected to describe those properties. Psychologists assume thereby that *concepts constitute a natural kind*. I call this assumption the *natural kind assumption*. This article challenges the natural kind assumption. It is argued that a growing body of evidence suggests that concepts do not constitute a natural kind. Hence, the notion of concept is inappropriate, if one aims at formulating scientifically relevant inductive generalizations about the human mind.

1. Introduction. In cognitive science, concepts are the bodies of knowledge that are stored in long-term memory and are used by default in the higher cognitive processes (categorization, inductive and deductive reasoning, analogy making, language understanding, etc.). Cognitive scientists assume typically that they constitute a *homogenous* class of mental representations. Of course, everybody recognizes that there are plenty of differences between concepts and also between kinds of concepts: DOG and CAT have different properties and so do folk biological concepts and concepts of artifacts. But it is assumed that over and above these differences, the mental representations that are used by default in our higher cognitive processes share a large number of properties. The goal of a psychological theory of concepts is to capture those properties. Since it is assumed that their properties explain many properties of our higher

cognitive processes, developing an adequate theory of concepts is viewed as a prerequisite for understanding higher cognition.

Such a view is nicely put by the psychologist Gregory Murphy in his recent survey of the psychology of concepts:

The psychology of concepts cannot by itself provide a full explanation of the concepts of all the different domains that psychologists are interested in. This book will not explore the psychology of concepts of persons, musical forms, numbers, physical motions, and political systems. *The details of each of these must be discovered by the specific disciplines that study them Nonetheless, the general processes of concept learning and representation may well be found in each of these domains.* For example, I would be quite surprised if concepts of musical forms did not follow a prototype structure (Chapter 2), did not have a preferred level of categorization (Chapter 7), and did not show differences depending on expertise or knowledge (Chapter 6). (2002, 2–3, my emphasis)

This view of concepts says essentially that *concepts constitute a natural kind*, that is, a class of entities about which many inductive generalizations can be formulated. I call the view that concepts constitute a natural kind the *natural kind assumption*.

The natural kind assumption is widely accepted by psychologists, philosophers of psychology, and more generally, cognitive scientists (sometimes explicitly, e.g., Medin et al. 2000, 123; Prinz 2002; Goldstone and Kersten 2003, 599). Arguably, it has been part and parcel of the psychology of concepts. Psychologists believe that with the notion of concept, they have identified one of the important classes for a scientific psychology—one of those classes that support the formulation of many inductive generalizations. Thus, for more than thirty years (Machery 2005), they have been looking for generalizations about members of this class.¹

Despite the widespread endorsement of the natural kind assumption, this paper sets out to challenge it. Indeed, I make a case for the following claim: A growing amount of evidence suggests that concepts do not constitute a natural kind. To put it differently, I claim that the bodies of knowledge that are used by default in our higher cognitive processes do not constitute a homogenous kind about which many inductive generalizations can be formulated. Thus, the notion of concept is not part of an adequate taxonomy of our mental representations, if one aims at for-

1. For reviews, see Smith and Medin 1981; Lambert and Shanks 1997; Murphy 2002; Goldstone and Kersten 2003. In philosophy of psychology, see Margolis 1994; Laurence and Margolis 1999; Prinz 2002.

mulating scientifically relevant inductive generalizations about the human mind.

Before going any further, I should discard a possible misunderstanding. In this paper, I am *not* addressing the usual questions raised about concepts by philosophers of mind. I take for granted the notion of concept that prevails in cognitive psychology—bodies of knowledge that are used by default in our higher cognitive processes. And I focus on a psychological question: Is the class of concepts a natural kind?

In the first section, I cast some light on the natural kind assumption, spelling out what properties the class of concepts should possess in order to be a natural kind. On this basis, I present in the second section the argument from explanatory necessity, which shows that the class of concepts does not possess these properties. In substance, this argument states that psychologists have to posit several kinds of concepts that have little in common in order to explain our higher cognitive processes. In the last two sections, I defend two premises of this argument. In the third section, I show that the main psychological theories of concepts have posited three theoretical entities that have little in common, namely, prototypes, exemplars, and theories. In the last section, I present some empirical evidence, drawn from the psychological research on concept combination, that we are justified in positing these three theoretical entities. I conclude that the natural kind assumption is misconceived.

2. The Natural Kind Assumption.

2.1. Natural Kind and Induction. The notion of natural kind is essentially enmeshed with the problem of induction (Mill [1843] 1905; Quine 1969; Boyd 1990, 1991; Hacking 1991). For, the notion of natural kind singles out those classes about which nonaccidental, scientifically relevant inductive generalizations can be formulated. With this notion, one draws a distinction between two kinds of classes: those about which inductive generalizations can be formulated, e.g., atoms, and those about which no or few generalizations can be formulated, e.g., things that weigh more than 124 kg. Thus, the members of a natural kind are supposed to share nonaccidentally a large number of (logically unrelated), scientifically important properties (or relations) beside the properties (or relations) that are used to identify them.

Since members of natural kinds have many properties in common, natural kinds are the building blocks of scientific generalizations. Many empirical sciences aim at identifying the natural kinds in their domain in order to develop adequate empirical theories. Psychology is no exception. Psychologists look for classes of entities about which scientifically relevant generalizations can be made. They introduce new notions to pick out

kinds that are believed to be natural (e.g., the notion of basic emotion) and they reject notions that turn out to pick out kinds that are not natural (Griffiths 1997).

2.2. Two Red Herrings: Essences and Laws. The basic idea presented above has been cashed out in many ways. Which account is best suited for my present purpose? Clearly, this account has to be applicable to psychological kinds and to allow many classes to be natural kinds. Otherwise, the denial of the natural kind assumption would simply be trivial.

Two accounts are thus inadequate. According to a common account, natural kinds are characterized by the possession of an essence, that is, a set of intrinsic, causally explanatory properties that are necessary and jointly sufficient to belong to the kind (Putnam 1975). However, it is unlikely that psychological kinds possess essences—at least, if the functionalist view is true. And this notion is excessively restrictive: for example, species wouldn't be natural kinds according to this account (Hull 1978). One might want to broaden the notion of essence, by including relational properties alongside intrinsic ones. However, the account of natural kind under consideration would remain unsatisfactory. For, it would not distinguish the properties that determine membership from the causally explanatory properties. However, in some natural kinds, the properties that are causally explanatory are not necessary conditions of membership, for not all members possess these properties. The class of political parties in democratic societies, which could be a natural kind in political theory, illustrates this point. The conditions of membership in this class are arguably different from the causal properties that explain why most democratic political parties share many properties.

According to another account, natural kind terms feature in laws, that is, in generalizations that are temporally and spatially unrestricted and that support counterfactuals (Collier 1996). Now, psychological kinds feature in *ceteris paribus* generalizations—not in laws (Fodor 1974). And, again, this notion is too restrictive: few kind terms feature in laws. One could propose to replace the notion of law by the notion of *ceteris paribus* generalization. This would be a step in the right direction, as we shall see below. However, an important element would still be missing from this account, namely the idea that there is at least one causal mechanism that accounts for these generalizations. This is an important aspect of the kinds scientists are interested in for inductive purposes.

2.3. The Causal Notion of Natural Kind. A broader notion has been developed by Richard Boyd (1990, 1991; Griffiths 1997).

A class *C* of entities is a natural kind if and only if there is a large

set of scientifically relevant properties such that C is the maximal class whose members tend to share these properties because of some causal mechanism.

The core idea of this definition is the following. A natural kind is a class about which many generalizations can be formulated: its members tend to have many properties in common. These generalizations are not accidental: there is at least one causal mechanism that explains why its members tend to have those properties. Finally, this class is not a subset of a larger class about which the same generalizations could be formulated.

One might object that 'large' is too vague. However, this complaint is unfounded. For the notion of natural kind, like the notion of heap, is vague. Even if there is no way to sharpen the idea of a 'large set of properties', it remains that the number of properties that can be projected from one subset of the class to the whole class is one dimension that distinguishes natural kinds from other classes.

Inversely, one might object that a class of entities that would share only few scientifically fundamental properties would be a natural kind. First, one can question whether such classes really exist. These fundamental properties would plausibly cause the members of these classes to share other properties. Moreover, if there were such classes, I would stick to my guns: they would *not* be natural kinds. For, they would be noticeably different from the paradigmatic natural kinds. Instead of stretching the notion of natural kind in order to include them, it would arguably be better to distinguish two types of scientific kinds: the natural kinds whose members share many properties and, say, the fundamental kinds, whose members share few fundamental properties.

In the present context, two aspects of the definition proposed above are important. First, the properties that characterize a natural kind are not necessarily possessed by *all* its members. It is only required that members of a natural kind *tend* to have these properties. Hence, natural kind terms don't have to feature in laws. It is only required that they feature in *ceteris paribus* generalizations.

Second, essences are only one of the possible causal mechanisms that explain why members of a natural kind share or tend to share many properties. Boyd (1990) has insisted upon the homeostasis of properties: in some natural kinds, the occurrence of a property causes the occurrence of other properties and is caused by their occurrence. Other mechanisms are possible, including common descent and social causes (Griffiths 1997).

2.4. The Natural Kind Assumption. The causal notion of natural kind is relevant for my present purpose. It allows psychological kinds to be natural kinds, since natural kinds do not have to possess essences nor to

feature in laws. Moreover, this notion has a large extension: substances, e.g., gold, physical entities, e.g., atoms, species, e.g., dogs, and artifacts do qualify as natural kinds. However, the causal notion of natural kind is not vacuous. It implies that nominal kinds, for instance, the class of physical objects that weigh more than 30 kg, are not natural kinds. For their members don't share many (scientifically relevant) properties. Moreover, it implies that many subsets of natural kinds, e.g., white dogs, are not natural kinds either. For the properties that are true of white dogs are true of all dogs (except *being white*).

In what follows, I use exclusively the causal notion of natural kind. Hence, the natural kind assumption says that the class of bodies of knowledge that are used by default in our higher cognitive processes possesses three characteristics:

- There is a large set of properties that these bodies of knowledge tend to possess.
- These bodies of knowledge possess these properties because of some causal mechanism.
- This set of properties is specific to this class of bodies of knowledge.

Importantly, psychologists who endorse the natural kind assumption are not committed to deny the existence of differences between concepts or kinds of concepts (Medin et al. 2000). For despite these differences, concepts may share a large set of properties.

2.5. The Received View. For more than thirty years, the cognitive psychology of concepts has been built on the view that concepts constitute a homogenous class about which specific, scientifically relevant generalizations can be formulated. Although some psychologists have recently have voiced some doubts (e.g., Ashby et al. 1998; Hahn and Chater 1998; Smith et al. 1998), many still endorse this view, particularly prototype theorists (e.g., Hampton 2001; Smith 2002), exemplar theorists (e.g., Juslin and Persson 2002; Zaki and Nosofky 2004), and theory theorists (e.g., Carey 2000). Barsalou and colleagues assume that most concepts, if not all, are perceptual symbols (Barsalou 1999). The recent search for hybrid models of concepts (see Section 6) suggests similarly that psychologists have not renounced the belief that concepts constitute a homogeneous class of representations. Several philosophers of psychology share this commitment. For instance, Prinz (2002) proposes that most concepts, if not all, are proxytypes, that is, context-sensitive perceptual representations.

Moreover, the received view has driven the methodology of the psychology of concepts and of the higher cognitive functions. In substance, psychologists have tried to find data that were easily accounted for by

their pet theory of concepts, but that were problematic for rival theories. Rival theories could account for these data only with ad hoc assumptions. Now, this methodology assumes that the class of concepts is homogenous and, therefore, that all the data about concepts have to be accounted for by a unique theory. This is tantamount to assuming the natural kind assumption.

3. The Argument from Explanatory Necessity.

3.1. *The Heterogeneity Hypothesis.* Given the causal notion of natural kind, there are three options to rebut the natural kind assumption:

- It could not be the case that the bodies of knowledge that are used by default in our higher cognitive processes have many properties in common.
- These mental representations could have many properties in common by accident.
- They could have those properties because they are a subset of a larger set of representations: no empirical generalization could be made specifically about them.

I propose that the available empirical evidence about our concepts supports strongly the first option: it is not the case that concepts have in common a large set of properties.

Indeed, I will argue that the class of concepts is divided into several kinds of representations that have little in common. I call this claim the *heterogeneity hypothesis*. There are several readings of this hypothesis. One could claim that different types of categories, say the folk biological categories and the artifact categories, are represented by different kinds of concepts and that these kinds have little in common. For example, there could be few properties common to DOG and TABLE, because in general, concepts of biological kinds and concepts of artifacts could have little in common. One could also claim that different cognitive processes are defined over different kinds of concepts and that these kinds have little in common. For example, a concept of dog used in the categorization process could have little in common with a concept of dog used in induction, because in general, concepts that are used in the categorization process and concepts that are used in the induction process could have little in common. I reject both readings.

Instead, I claim that most categories are represented by several concepts that belong to kinds that have little in common. For example, we have several concepts of dog, each of which belongs to a different kind of concepts. There are few properties common to these concepts because in general, the corresponding kinds of concepts have little in common. I call

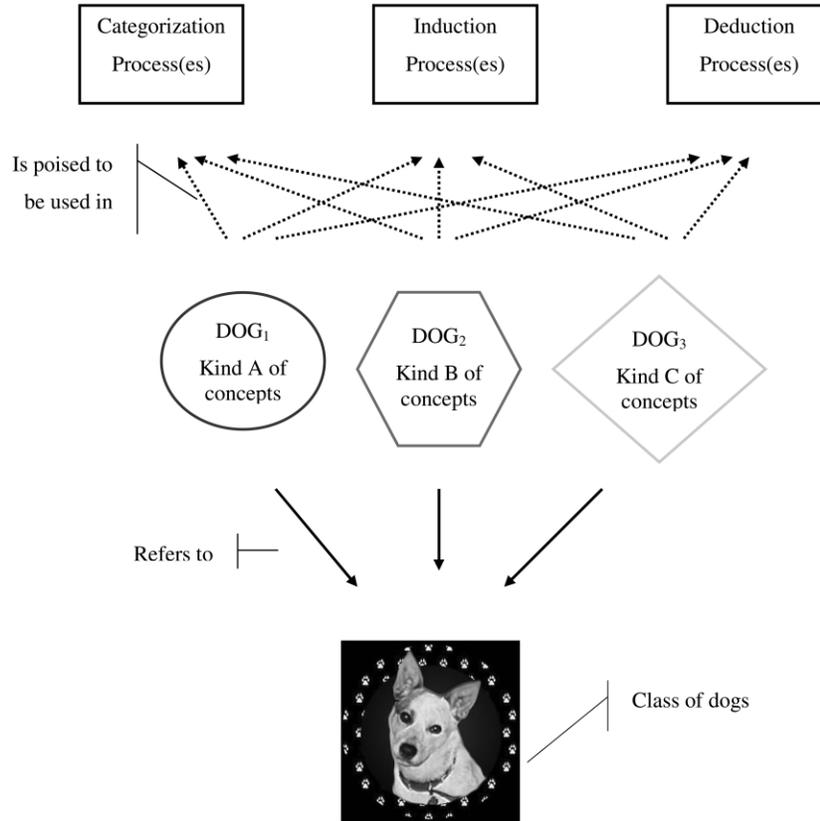

Figure 1. The heterogeneity hypothesis.

these kinds the *basic kinds of concepts*. Each of these concepts of dog can be used in our higher cognitive processes. We can use DOG_1 , DOG_2 , DOG_3 , . . . , to categorize, to reason inductively, to reason deductively, etc. They qualify as concepts because they are poised to be used in our higher cognitive processes. They are bodies of knowledge that are used *by default* by our higher cognitive processes. Save for specific circumstances, we rely on these bodies of knowledge, when we decide whether something is a dog, when we reason about dogs, etc. Beliefs about dogs that are not part of these bodies of knowledge can be used in our cognitive processes as well. However, they are not used by default by our higher cognitive processes, when we think about dogs. They are retrieved from long-term memory merely occasionally. This version of the heterogeneity hypothesis is summarized by Figure 1.

This view of our higher cognition stands in sharp contrast with the received view. Our higher cognitive processes are not defined over a homogenous class of mental representations. Thus, the class of concepts is not useful to draw scientifically relevant generalizations about our mental representations. Instead of trying unproductively to characterize the properties that are generally possessed by concepts, psychologists and other cognitive scientists' explicit goal should be to characterize each basic kind of concepts. I submit that the properties that are characteristic of each basic kind of concepts are not characteristic of the other basic kinds. These basic kinds of concepts are the right level for theorizing about our mental representations.

Some might object that we knew all along that we use different kinds of knowledge in our higher cognitive processes. Isn't it obvious that we can use any kind of knowledge to decide whether something is a dog? Granted. But this objection is beside the point. For the claim is (i) that we have specific bodies of knowledge in our mind *that are used by default in our cognitive processes* and (ii) that these bodies of knowledge divide *into different kinds that have little in common*. That we may use any kind of information in our higher cognitive processes does not say anything about the class of bodies of knowledge that are used *by default* in our higher cognitive processes. Psychologists and some philosophers of psychology aim at formulating generalizations about this class, assuming thereby that it is homogeneous. I deny this claim.

3.2. *The Argument from Explanatory Necessity.* It is now possible to state the following argument against the natural kind assumption:

The Argument from Explanatory Necessity.

1. Concepts, that is, the bodies of knowledge used by default in our higher cognitive processes, are posited in order to explain the properties of these processes.
2. The theoretical constructs posited by the main theories of concepts have little in common.
3. In order to explain the properties of our higher cognitive processes, we need to assume that all of these theoretical constructs are used by default in our higher cognitive processes.
4. Hence, our higher cognitive processes use several kinds of representations that have little in common.
5. Hence, concepts are not a natural kind.

The core idea of this argument is straightforward. Concepts are theoretical entities that are posited in order to explain the properties of our

higher cognitive processes. In order to provide a satisfactory explanation, we have to posit several kinds of concepts that have little in common. Which ones? At least those that have been assumed by the main paradigms of concepts in the recent psychological literature.

Clearly, this argument is *empirical*. The truth of Premise 3 is an empirical question. Thus, the whole argument claims that the available empirical evidence about concepts and about the higher cognitive processes supports the denial of the natural kind assumption. Since this argument is empirical, new empirical data could result in a different conclusion.

I will take Premise 1 for granted. Almost all psychologists and many philosophers of psychology (e.g., Prinz 2002) assume it. Concepts are those bodies of knowledge that we use by default in our higher cognitive processes. Their properties explain how we reason, how we categorize, etc. In what follows, I argue for Premises 2 and 3.

4. Three Kinds of Representations That Have Little in Common. In this section, I defend the second premise of the argument from explanatory necessity. I first present the three main paradigms of concepts in the contemporary literature on concepts. Then, I show that they posit three theoretical constructs that have little in common.

4.1. Three Theoretical Entities: Prototypes, Exemplars, Theories. Since the rejection of the classical view of concepts in the 1970s, cognitive psychology has produced three main views, the prototype view of concepts, the exemplar view of concepts, and the theory view of concepts.²

The prototype view of concepts is built around the idea that concepts are prototypes³ (e.g., Rosch and Mervis 1975; Smith et al. 1988; Smith and Minda 2002):

A concept of a class of objects is a *prototype*, i.e., a body of knowledge that contains some statistical information about the properties possessed by the members of this class, particularly, about the properties possessed by most members of this class.

Prototypes single out the properties of the members of the denoted categories in *statistical* terms. In most prototype models (but not in all), prototypes are assumed to encode some information about the *typical* properties of the denoted category, that is, the properties that are judged

2. There are other views of concepts (e.g., Barsalou 1999; Prinz 2002). However, the argument is strengthened if we have to admit a fourth basic kind of mental representations (provided that it has little in common with the other basic kinds).

3. The term 'prototype' is used ambiguously to design the best member of a category and the representation of a category. I use the term in this second sense.

to be possessed by *most* members of the category. Importantly, these properties are not judged to be necessary. For example, to have a concept of dog is to think by default of dogs as having generally, but not necessarily, such form, as having generally a tail, etc.

According to the exemplar view of concepts, our higher cognitive processes are defined over representations of specific category members, which stand for the whole category (e.g., Medin and Shaffer 1978; Nosofsky 1988; Juslin and Persson 2002).

A concept of a class of objects consists of a *set of exemplars*, i.e., of representations of particular members of this class.⁴

For example, to have a concept of dog is to think by default of dogs as being the class of entities that are similar to Fido, Pluto, and Spot and to use these individual representations to reason about dogs in general.

According to the theory view of concepts, our mental representations are similar to scientific theories and our higher cognitive processes are similar to scientific forms of reasoning (Murphy and Medin 1985; Carey 1985; Keil 1989; Gopnik and Meltzoff 1997; Keil and Wilson 2000). The theory view is often put very loosely in the empirical literature. One finds usually two ideas: (i) concepts are enmeshed within theories and (ii) concepts are theories. I am interested in the second claim.

A concept of a class of entities is a *theory* about this class, that is, a body of knowledge that contains some nomological, causal, modal and functional generalizations about this class

To possess a concept of dog is to think by default of dogs as being the class of entities that satisfy some kind of theory, i.e., some nomological, modal, causal and functional generalizations (e.g., a theoretical concept of dog may say of dogs that they necessarily engender individuals that belong to the same species).

4.2. Prototypes, Exemplars and Theories Have Little in Common. The claim is that *these* three theoretical constructs have little in common. Now, how does one evaluate how different various kinds of mental representations are? Clearly, exemplars, theories and prototypes have plenty of irrelevant properties in common, for example *not being cups of tea*. What matters, however, are those properties that psychologists take to be im-

4. In the literature, exemplars are taken to represent either *individuals* or specific *encounters* with individuals. In the first case, human beings have one representation for each (represented) member of a category. I have one exemplar of Fido, another one of Spot, etc. In the second case, whenever I meet Fido, I produce a new exemplar (Nosofsky 1988). I favor the first idea.

portant when they characterize mental representations. Psychologists focus on the representational properties of mental representations and on their functional properties, i.e., what mental representations represent and how they are used in cognitive processes. Hence, if exemplars, prototypes and theories have different representational and functional properties, this would suggest that they have little in common. Of course, other properties, for example neural properties, may turn out to be important to characterize representations. Then, we would have to reevaluate the denial of the natural kind assumption.

I argue first that prototypes, exemplars, and theories are assumed to encode three different types of knowledge. According to exemplar theorists, applying a concept to an individual is tantamount to thinking that this individual is similar to some specific individuals, which are themselves described as having such and such properties. Thus, the mind stores some information about the properties of specific individuals, for example, some descriptions of Fido and Spot.

According to prototype theorists, applying a concept to an individual is tantamount to thinking that this individual possesses to a sufficient degree a sufficient number of typical properties. Thus, the mind stores some statistical information about the properties that characterize classes of individuals (some prototype theories are more complex).

According to theory theorists, applying a concept to an individual is tantamount to thinking that this individual possesses some properties either with some modal force, or because of some law, or for some causal or functional reason. Thus, the mind is storing some modal, nomological, causal, and functional information about classes of individuals.

Notice that for most categories, it is possible to encode some information about the typical properties of their members, some modal, nomological and causal information about their members and some information about the properties possessed by some of their members. Hence, most categories could be represented by a prototype, a theory and a set of exemplars.

I argue now that prototypes, exemplars and theories are assumed to be used in three different kinds of cognitive process. Exemplar theorists and prototype theorists suppose that the higher cognitive processes involve the computation of the similarity between some representations, and respectively, sets of exemplars and prototypes. To make this idea a bit more concrete, consider how a prototype theorist might explain the categorization process. Peter sees a dog. He forms a representation that attributes some properties to this dog. The properties that are attributed are matched with the properties that are represented by several prototypes, including the prototype of dog. The similarity between the dog and each prototype is computed. Since the similarity between the dog and the prototype of

dog is higher than the similarity between the dog and the other prototypes, Peter concludes that he is seeing a dog. Various properties of our other higher cognitive processes are similarly explained (see Osherson et al. 1990 on induction; Hampton 1982, 1988 and Sloman 1998 on deduction; Smith and Osherson 1989 on probabilistic reasoning).

Advocates of the exemplar view would provide a similar explanation of the categorization process, except that the dog would be compared to sets of exemplars, instead of prototypes (Nosofsky 1988). Many properties of the other higher cognitive processes could be similarly explained (e.g., Juslin and Persson 2002).

Advocates of the prototype view and of the exemplar view agree on the role of similarity in our cognitive processes. However, they assume different ways of computing the similarity between a represented object, and respectively, prototypes and sets of exemplars. In brief, prototype theorists assume that the similarity measure is a linear function of the number of properties common to the concept and the object to be categorized, while exemplar theorists take it to be a nonlinear function.

The theory view of concepts assumes that our higher cognitive processes do not rely on similarity. On the contrary, they are supposed to be similar to the reasoning processes that are used in science. Since theory theorists are less concerned with our cognitive processes than prototype and exemplar theorists, their views about our cognitive processes are less developed. Theory theorists often compare our reasoning processes to explanations (Keil and Wilson 2000) or to inferences to the best explanation (Murphy and Medin 1985). They generally assume that our cognitive processes follow the standard rules of logic and of probabilistic reasoning (Smith et al. 1992).

Murphy and Medin (1985) provide the following toy example. If at a party, a guest jumps in the swimming pool entirely dressed, we may conclude that she is drunk. This categorization does not rest on any matching between our concept of drunk people and our singular representation of this guest. On the contrary, we infer that the most plausible explanation of the behavior of this guest is that she is drunk. This inference is supposed to follow the rules of probabilistic inference.

Finally, it is important to notice that the heterogeneity hypothesis suggests that several cognitive processes underlie categorization, several processes underlie inductive reasoning, and so on. If prototypes, exemplars and theories all exist, and if prototypes, exemplars, and theories are usually used in different types of cognitive process, then we have plausibly several ways to categorize, to draw an induction, and so on. To put it a bit differently, we would have several categorization processes (or several induction processes, etc.), which would use different kinds of representations. This suggestion raises an exciting, but yet understudied question:

How do these cognitive processes interact or compete? To illustrate, when we categorize, how do our prototype-based categorization process, our exemplar-based categorization process, and our theory-based categorization process interact, if they do? This is a topic for further research.

I have shown first that prototypes, exemplars and theories are assumed to possess different representational properties. I have also shown that they are assumed to possess different functional properties. Hence, given the properties that are relevant to characterize mental representations, I conclude that the main psychological theories of concepts assume three kinds of mental representations that have little in common. *This conclusion supports Premise 2.* In other words, I have established the following *conditional* claim: if it can be shown that prototypes, exemplars, and theories exist and are used by default in our higher cognitive processes, then concepts are not a natural kind.

5. Concept Combination and the Natural Kind Assumption. I propose that we need to posit the three kinds of representations described above. It is of course impossible to review in this article the large body of evidence that supports this claim. In this section, I focus instead on a specific cognitive competence, the capacity to combine concepts. Since Osherson and Smith's seminal study (1981), concept combination has been a hot topic among psychologists of concepts (see the reviews in Hampton 1997 and Murphy 2002, chap. 12). Their results suggest that concept combination requires the kinds of knowledge that exemplars, prototypes and theories are assumed to represent. This is evidence for Premise 3 of the argument from explanatory necessity.⁵

5.1. Concept Combination. Concept combination is the capacity to form new bodies of knowledge about classes for which we have no concept permanently stored in long-term memory. Those representations, e.g., GRANDMOTHER SPY, are formed on the basis of other representations stored in long-term memory, e.g., GRANDMOTHER and SPY. A concept is simple if and only if it is a permanent body of knowledge in long-term memory. There is a finite stock of simple concepts. A complex concept is not stored permanently in long-term memory, but has to be produced on the fly for various cognitive purposes (e.g., for language comprehension, reasoning, etc.).⁶ The claim that concepts combine means

5. How psychologists' empirical work on concept combination relates to the compositionality arguments in philosophy of mind (Fodor 1998) is an important topic that awaits further research (but see Prinz 2002).

6. Because complex expressions like "red wine" are common, they may express concepts that are permanently stored in long-term memory, that is, simple concepts (Rips 1995).

that there is a mental mechanism that operates on simple concepts to produce complex concepts (or on less complex concepts to produce more complex concepts).⁷

To understand concept combination is to characterize the processes that underlie the creation of a new body of knowledge out of the bodies of knowledge that are stored in long term memory. As a result, we would explain why some information turns out to be represented by complex concepts. The claim defended here is that in order to explain concept combination, one has to assume the storage of prototypes, exemplars, and theories in long-term memory.

5.2. Prototypes and Property Inheritance. When subjects are given two expressions, say “Oxford graduate students” and “carpenter,” and they are asked to list the properties that are typical of Oxford graduate students who are carpenters, they often find the task meaningful and easy (Hampton 1987; Kunda et al. 1990; Johnson and Keil 2000). In some experiments, they are also asked to determine which properties are typical of the two original categories, in our example, Oxford graduate students and carpenters (Hampton 1987; Johnson and Keil 2000). The psychologist James Hampton has shown that there is a correlation between the properties that are judged to be typical of the members of the original categories, Oxford graduate students and carpenters, and the properties that are judged to be typical of the members of the resulting category, Oxford graduate students who are carpenters (Hampton 1987).

This correlation suggests that the creation of a complex concept involves determining which properties are typical of the denoted category, Oxford graduate students who are carpenters, on the basis of the typical properties of the original categories, Oxford graduate students and carpenters. Now, prototypes are supposed to encode the knowledge about typical properties. Thus, it is plausible that when we produce on the fly a complex concept, we retrieve the prototypes of the original categories and we transmit some of the typical properties they represent to the complex concept. This is known as *property inheritance* (Hampton 1997). The inheritance of properties by the complex concept is (partly, as we shall see) driven by the assumption that the typical properties of the categories denoted by the compounded concepts are also typical of the category denoted by the complex concept. Notice that I am not claiming that complex concepts are prototypes. Although complex concepts do encode some information about the typical properties of the denoted

7. There are several types of concept combination. “Oxford graduate student that is a carpenter” (Hampton 1987) and “red bicycle” (Smith et al. 1988) expresses arguably two different types of complex concepts.

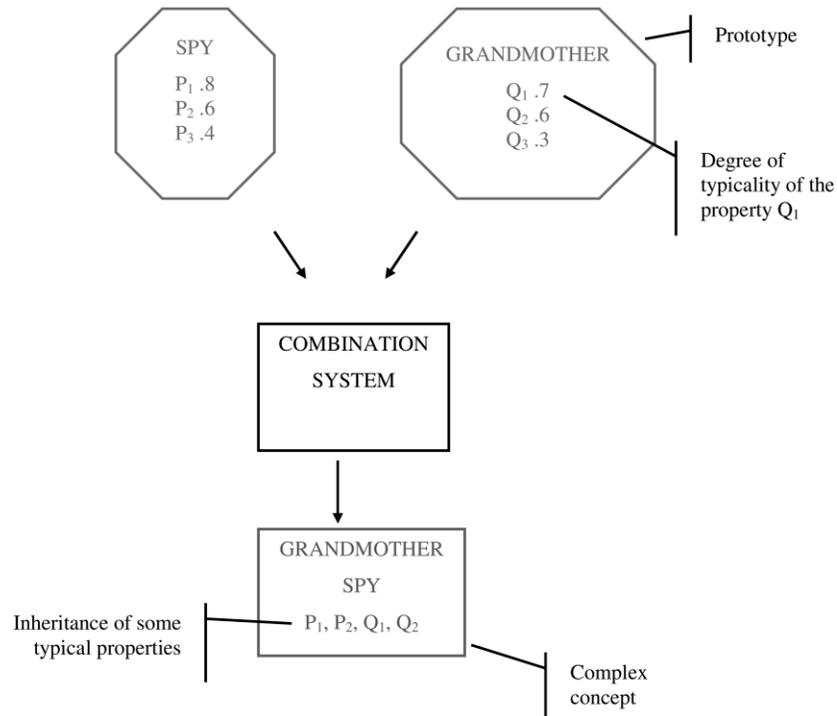

Figure 2. Property inheritance.

categories, as do prototypes, they may also encode some modal and some causal information—see below. Property inheritance is summarized by Figure 2.

One might object that the results described above tell something about concept combination only if it can be shown that our beliefs about the properties that are judged to be typical of Oxford graduate students who are carpenters constitute a concept, that is, if they are used in our higher cognitive processes. Otherwise, these results would not bear on the creation of complex concepts. Now, several phenomena suggest that these beliefs are indeed used by our cognitive processes. Particularly, subjects are able to evaluate the typicality of individuals qua Oxford graduate students who are carpenters (e.g., Medin and Shoben 1988). That is, when subjects are given the description of an individual, they are able to determine whether this individual is a typical Oxford graduate student who is a carpenter. This suggests that people use their beliefs about which properties are typical of Oxford graduate students who are carpenters to evaluate the typicality of individuals.

One might reply that these typicality judgments are based on the typicality of these individuals qua Oxford graduate students and on their typicality qua carpenters (Huttenlocher and Hedges 1994). That is, we may judge that an individual is a typical Oxford graduate student who is a carpenter, if we judge that she is a typical Oxford graduate student and a typical carpenter. Hence, these judgments may not rely on a complex concept that represents the typical properties of Oxford graduate students who are carpenters. In other words, to judge whether an individual is a typical Oxford graduate student who is a carpenter, we may not need to produce a complex concept, OXFORD GRADUATE STUDENT WHO IS A CARPENTER. This objection fails, however. For, the typicality of items with respect to a complex concept (OXFORD GRADUATE STUDENT WHO IS A CARPENTER) is often not a function of their typicality with respect to the combined concepts (OXFORD GRADUATE STUDENT and CARPENTER). The former is a function of the latter only when the membership in one category (Oxford graduate students) is believed to be independent from the membership in the other (carpenters) (Hampton 1987, 57; Huttenlocher and Hedges 1994). Hence, the best explanation of the typicality judgments under consideration is that subjects do produce a complex concept that represents typical properties and use this complex concept to make typicality judgments. Together with other phenomena (Hampton 1982, 1987, 1988, 1996), this discussion suggests that we produce complex concepts by retrieving prototypes from our long-term memory.

5.3. *Theories and Property Inheritance.* The story is however more complex, for psychologists have shown that the typicality of a property is not the only factor that determines whether it is represented by the complex concept. To illustrate, whether the property *being ambitious* is typical of Oxford graduate students and of carpenters is not the only factor that determines whether it is represented by the complex concept OXFORD GRADUATE STUDENT WHO IS A CARPENTER. Property inheritance is also influenced by our *theoretical* knowledge about the categories that are combined (Medin and Shoben 1988; Murphy 1988, 1990; Rips 1995; Johnson and Keil 2000).

Concept combination uses some *modal* information about the properties of the original categories, for example, about the properties of grandmothers and of spies. Which properties are represented by the complex concept, GRANDMOTHER SPY, is a function of their modal force. Studies show that if the input concepts represent *impossible* properties (properties that are typically possessed by the members of one category, say *male* for spies, but that are believed to be impossible for the members of the other category, say grandmothers), these are never represented by

the complex concept; if the input concepts represent *necessary* properties (properties that are believed to be necessarily possessed by the members of one category, say *being the mother of a parent* for grandmothers), these properties are always represented by the complex concept (Hampton 1987).

Moreover, concept combination requires some *causal* information about the properties of the original categories (Medin and Shoben 1988; Murphy 1988, 1990; Johnson and Keil 2000). So-called *central properties* are preferentially represented by complex concepts. A property is central when it explains causally the possession of other properties. For example, *being curved* is a central property of boomerangs because subjects believe that boomerangs come back because they are curved. *Being made out of wood* is less central because it explains few properties of boomerangs.⁸

These results show that during concept combination, we access some modal and causal knowledge. Now, prototypes do not represent any modal nor any causal knowledge, but only some statistical knowledge. Consequently, during concept combination, we access some knowledge that is not represented by prototypes. Theories are precisely supposed to represent this form of knowledge. Thus, to account for concept combination, we need to posit a second type of concepts, i.e., theories, beside prototypes.

Not so easily, however. For, one could object that the evidence does not show that we have some theoretical *concepts*, that is, bodies of theoretical knowledge that are used by default in a large number of cognitive tasks. We may simply rely on some background modal and causal knowledge about the categories that are combined. This is indeed how Hampton himself thinks of the use of modal knowledge in concept combination (Hampton 1997). Being a prototype theorist, he believes that this modal knowledge is specifically extracted for the purpose of building complex concepts. Hence, this modal knowledge is not used by default in our cognitive processes. I disagree with this interpretation of the evidence. For, we routinely use this very same causal and modal knowledge in other higher cognitive processes (see Keil 1989 on categorization; Coley et al. 1999 on inductive reasoning). The theoretical knowledge that is used in concept combination is poised for being used in many cognitive processes. Thus, the bodies of knowledge that encode this knowledge are concepts.

5.4. *Emergent Properties, Exemplars, and Theories.* Not all properties

8. In the literature, it is unclear how the complex concept represents the causal and the modal knowledge. What is clear is that these two types of knowledge affect the creation of complex concepts.

that are represented by a complex concept are represented by the original prototypes. The properties not represented by the original prototypes are said to be emergent and this phenomenon is known as *property emergence* (Hampton 1987, 1997; Kunda et al. 1990; Johnson and Keil 2000; Costello and Keane 2000). For example, Oxford graduate students who are carpenters may be judged to have an artistic character, while neither Oxford graduate students nor carpenters are judged to have an artistic character (Kunda et al. 1990). Several explanations of property emergence have been suggested. They are not mutually exclusive. For the sake of argument, I focus on the explanation that relies on exemplars.

Some properties derive from our knowledge of specific members of the complex category (Hampton 1987; Medin and Shoben 1988, 183). For example, if a subject has to produce on the fly a complex concept like PRESIDENT FROM TEXAS, she may look in her long-term memory for someone who is president and who comes from Texas. Plausibly, she would retrieve the singular representation of G. W. Bush and she would transmit to the complex concept the properties that are represented by this singular memory. She would thus represent presidents from Texas as being right-wing. Hence, concept combination accesses some singular representations. This suggests that these may be poised to be used in our higher cognitive processes, that is, that they are concepts.

5.5. *Consequences.* Empirical evidence suggests that concept combination rests on three kinds of knowledge: some statistical knowledge about the typical properties of the relevant categories, some causal and modal knowledge about these categories, and some knowledge about some members of these categories. Prototypes, theories and exemplars are respectively supposed to encode these kinds of knowledge. Since other cognitive processes rely also on these bodies of knowledge, they qualify as concepts. This conclusion is evidence for Premise 3 of the argument from explanatory necessity: in order to explain concept combination, we need to assume that prototypes, exemplars and theories exist.

6. Objections. For the sake of space, I cannot deal at length with the possible objections. For the time being, I merely mention the most prominent ones and sketch some answers.

One could first concede that psychologists need to assume the existence of prototypes, of exemplars, and of theories to explain the empirical evidence. But one would then argue that concepts are prototypes, while exemplars and theories are merely part of our background knowledge, or instead, that concepts are exemplars, while prototypes and theories are merely part of our background knowledge, and so on.

I have dealt with this objection earlier. In brief, exemplars and theories

qualify as concepts alongside prototypes, because they are retrieved by default from our long-term memory to solve a large number of tasks.

One could also question whether we really need to posit prototypes, exemplars and theories to explain the available evidence. In the categorization literature, most psychologists believe that to account for the data, exemplars (Zaki and Nosofsky 2004) or prototypes that represent property correlations and category variability (Barsalou 1990; Hampton 2001) are sufficient.

This second objection fails, however. Prototype theorists deny that exemplars account for all the categorization data, and vice versa (e.g., Smith and Minda 2002; Zaki and Nosofsky 2004). To account for the data about human categorization, including neuroimaging data (e.g., Smith et al. 1998) and the performances of amnesic patients (Knowlton 1999; but see Zaki and Nosofsky 2004), one has plausibly to posit both prototypes and exemplars. Moreover, if one takes into consideration other cognitive competences, the need for both types of concepts is even more pressing. For instance, singular representations are often used in reasoning (see the study of case-based reasoning, e.g., Hammond 1989) alongside prototypes (e.g., Osherson et al. 1990) and theories (e.g., Keil and Wilson 2000).

Third, one could argue that theories, exemplars, and prototypes have much in common: they denote categories, they store some knowledge about categories, they are used in induction, in categorization, they are acquired through experience, etc. Hence, the class of concepts is a natural kind.

This objection misconceives the nature of natural kinds. Members of a natural kind have many properties in common beside those properties that are used to identify the kind. This is not the case of concepts. Most of the properties mentioned in the objection are used to identify the class of concepts. Moreover, psychologists are *not* interested in the properties mentioned in the objection. What psychologists want to find out is not that concepts store some knowledge about categories, but what kind of knowledge is stored. Similarly, the fact that concepts can be used in induction (or in categorization, or learned through experience . . .) is not a generalization that is of much interest for psychologists. What they want to know is how concepts are used to solve inductive tasks, to categorize or how they are learned. Now, the class of concepts is inadequate for drawing generalizations concerning what kind of knowledge is by default available in long-term memory, how we solve inductive tasks, how we categorize, and so on. That is, the class of concepts is inadequate for drawing the generalizations psychologists are interested in. Thus, the class of concepts is not a natural kind.

Finally, one could argue that the evidence shows that each concept is

constituted by three elements, or parts—a prototype, a set of exemplars and a theory, not that each category is represented by several concepts.

A similar idea was developed under the name ‘dual theories of concepts’ at the end of the seventies (e.g., Osherson and Smith 1981). More recently, some psychologists have developed new hybrid theories of concepts (e.g., Gelman 2004). Spelling out these views and evaluating them would require a lengthy treatment. In brief, I claim that most of them are terminological variants of the heterogeneity hypothesis, for psychologists are interested in the properties of the parts. To the extent that they differ from the heterogeneity hypothesis, for instance by insisting that one part is more central than the others, I claim that little evidence supports them.

7. Conclusion. Most psychologists of concepts and of the higher cognitive functions (categorization, induction, etc.)—particularly, prototype theorists, exemplar theorists and theory theorists—as well as some philosophers endorse the received view: despite differences between kinds of concepts, many scientifically interesting properties are true of most, if not all, concepts. Thus, the class of concepts is supposed to be central for a scientific psychology: it is the proper level to formulate inductive generalizations about the bodies of knowledge that are used by default in our higher cognitive processes. In brief, it is a natural kind (the natural kind assumption).

In this article, I intended to rebut the natural kind assumption. I propose that the class of concepts divides into kinds that have little in common (the heterogeneity hypothesis). It may be useful to reformulate the argument. The three main psychological theories of concepts posit three kinds of representations, exemplars, theories, and prototypes. These theoretical constructs do not share a large set of scientifically relevant properties: they are supposed to encode different kinds of knowledge and to be used in different types of cognitive process (Section 4). Now, the research on an important cognitive process, concept combination, suggests that we need to assume the existence of these three theoretical constructs (Section 5). A careful study of the empirical literature on concepts shows that the research on other higher cognitive processes leads to the same conclusion. Hence, the bodies of knowledge that are used by default in our higher cognitive processes have little in common. Since concepts are these bodies of knowledge, the class of concepts encompasses several kinds of mental representations that have little in common (the argument from explanatory necessity). Hence, even on the broadest notion of natural kind, *concepts are not a natural kind*.

The implications of this conclusion are far-reaching. Although for the sake of space, I cannot elaborate here, I present the most important ones. First, the notion of concept is ill-suited to formulate scientifically relevant

generalizations about the mind. Psychologists should focus instead on other classes of mental representations, particularly prototypes, exemplars, and theories (and eventually others). Second, the controversy between the main psychological theories of concepts is deeply misguided. Concepts are neither prototypes, nor exemplars, nor theories. Some concepts are prototypes, some concepts are sets of exemplars, some concepts are theories. The theory view of concepts, the prototype view of concepts and the exemplar view of concepts are not inconsistent theories about our concepts: instead, they characterize the main features of three basic kinds of representations. Finally, the rebuttal of the natural kind assumption raises a provocative question: if the notion of concept is ill-suited for scientific purposes, do we need it at all? But this is certainly a topic for another day.
