Campaign Rhetoric and the Hide-&-Seek Game

Abstract

We present a model of political campaigning where a candidate chooses between promoting oneself (positive campaign) or attacking the rival (negative campaign). Campaign choices determine the subject of public deliberation: If a candidate runs a positive campaign and his rival a negative campaign, the voters learn the quality of the “focal” candidate. Thus, negative campaigns may be used either to expose the rival candidate (informative role) or to turn attention away from oneself (non-informative role). The effect of negative campaigns depends on whether it is faced with another negative campaign (cross talk) or a positive campaign (fruitful debate). We suggest that in order to ascertain the effect of negative advertising, studies should take into account the campaigns employed by both candidates. Voter expectation about candidate quality plays a major role in campaign selection: while the incidence of negative campaigning goes down as the expected prior improves, the probability of selection of the correct candidate is non-monotonic in the said prior.

1 Introduction

Electoral campaigns are possibly the most important element of voters’ information about the candidates. However, campaigns do not contain disinterested, impartial information. Candidates choose their rhetoric strategically in order to influence voter perception. One aspect of such strategic choice that has received considerable attention both in the media and in the academy is the choice between positive and negative advertising: whether to highlight one’s own quality or to focus on why the rival is unsuitable for office. While every electoral campaign involves a

Any error that remains in the paper is my responsibility.
large number of positive, negative and (especially) comparative messages, we shall characterize
the overall theme of a campaign as broadly positive or negative, and it is the choice of this theme
that we shall examine in this paper.\footnote{While some of the literature has looked at the role of individual messages, a large chunk of the empirical
literature has “coded” campaigns as either primarily positive or primarily negative or the extent to which a whole
campaign is negative. Ansolabehere et al, in their seminal study of turnout in 34 senate elections in 1992, use the
binary characterization and others (e.g., Brooks (2006) and Wattenberg and Brians (1999)) have used the same
data.}

In this paper, we think of campaigns as public debates in which the voting public forms its
judgement about the candidates by comparing and contrasting their campaign statements. Thus,
the nature and extent of information revealed about candidates depends jointly on the campaign
themes chosen by both candidates. In particular, our main premise is that If one candidate decides
to highlight why he is suitable (positive campaign) and the other argues why his rival is unsuitable
(negative campaign), then the former candidate is the focal one in the electoral race: the public
learns more about his quality than about the other one. This creates the main tension that we
study in the paper: while good candidates try to reveal information through focality and the bad
ones trying to avoid focality. The analysis borrows its basic idea from the literature on issue choice
in campaign rhetoric (Simon, 2002; Kaplan et al, 2006; and Egorov, 2012): more information is
revealed about an issue if the two candidates discuss both sides of the issue rather than if only one
candidate presents his side of the issue. In this paper, we study the candidate’s decision to focus
on one of two decidedly aggregate issues: matters pertaining to one’s own suitability for office vs
those pertaining to the rival’s quality. Such a model allows us to analyze conditions under which
negative advertising is used to inform the electorate or to muddle the debate.

Opinions are deeply divided regarding whether the practice of negative campaigning improves
or degrades the electoral process. While some view negative campaigns as essentially vicious mud-
slinging with the effect of reducing turnout (Ansolabehere and Iyengar 1995, Ansolabehere et al
1994, 1999), destroying voters’ trust in government and undermining the efficacy of the political
system (Brader 2005), others (Geer 2006) have pointed out its role in providing genuine information
and disciplining the candidates, and even in stimulating turnout (Freedman and Goldstein 1999,
last two decades, there has been a profusion of empirical and experimental research examining
these effects. However, in a meta-study covering 110 articles, dissertations and books published
on the topic between 1987 and 2007, Lau et al (2007) finds that there is no consensus in the
literature on the role of negative advertising (see also Lau et al 1999). All empirical or experimental
work aimed at uncovering the role of negativity in advertising has so far looked at the effect of
individual messages/campaigns in isolation - our model postulates that we may get a clearer and
more nuanced picture if future work takes into account both the campaign themes (or messages)
in contention.

There is a wide variation in the definition of negative advertising employed in the literature.
At one extreme, Ansolabehere and Iyengar (1995) equates negative advertising with mudslinging and ad hominem attacks; and at the other extreme, Polborn and Yi (2006), henceforth referred to as PY, has defined negative advertising exclusively as provision of valuable electoral information about the rival candidate. We use a broad definition of negative and positive campaigns that is adopted from Finkel and Geer (1998): “[P]ositive appeals are ones that candidates offer to promote themselves on some issue or trait.”; and “Negative appeals are attacks [or criticism] leveled at the opposition.” While this definition literally applies to specific messages, we adjust this definition for aggregate campaign themes. In our model, a positive campaign may contain messages about one’s own strength of character, values, records and arguments about why one’s position on different issues is close to that of the median voter. On the other hand, a negative campaign may contain a series of messages regarding the opponent’s features (character flaws, vices, inconsistencies, past failures) and arguments why his political positions are not close to that of the median voter. In sum, the crucial difference between a positive and negative campaign is whether the informational spotlight is focused on oneself or on the rival. According to this definition, there is nothing inherently negative about talking about oneself or on the rival. However, it is never in the interest of a candidate to highlight his own failings or his rival’s virtues: therefore, self-focused campaigns typically contain positive information and rival-focused campaigns contain negative information.

Given this categorization of campaign themes, whether negative advertising is useful or harmful to the voter arises endogenously from candidate choices. When one candidate goes positive and the other negative, the former candidate’s quality is the focal issue: the candidates engage in an active debate about this issue. The voters learn about the focal candidate by comparing claims and counterclaims. Most of the pre-electoral discussions in the public sphere are centered on the focal candidate. Two recent examples of focal candidates in high profile elections are Barack Obama in the American Presidential Election of 2008 and Narendra Modi in the Indian Lok Sabha election of 2014. Compared to the focal candidate, a lot less is learnt about the rival in such elections. Not every election has a focal candidate, however. If both candidates run positive campaigns or both employ negative campaigns, they are essentially “talking past each other”. There is a lot less issue engagement in this case. Since there are only one-sided claims which are less credible, the voters learn a lot less about either candidate in this case.

As the campaign watchdog, the media has an important role to play in our story. Following PY, we think of the candidates as setting the agenda for the media through their choice of campaign themes. The media checks the veracity of statements made by the candidates, compares claims and counterclaims and produces a judgement on the issue being debated. Given the constraints on the time, space and resources of the media, fact-checking more efficient when there is concentrated engagement about one candidate rather than a diffused discussion about both candidates.

Scholars studying American political campaigns have long stressed the need for issue engagement (or “dialogue”) for enabling the voting public to make an informed decision. Berelson et al
(1954), Kelley (1960), and more recently Petrocik (1996) and Sellers (1998) document and bemoan the tendency of candidates to talk past each other. Simon (2002) defines “dialogue occurs only when two candidates address the same subject...the opposite of dialogue is ignoring, responding by discussing a different subject”. Emphasizing that “the level of dialogue approximates the quality of the campaign”, he goes on to observe that the “decision to dialogue can be construed as a strategic choice”. This strategic choice is formally modelled by Simon (2002), Kaplan et al (2006) and Egorov (2012) where they assume that voters learn more about issues over which candidates choose to engage in a dialogue. Simon (2002) and Kaplan et al (2006) also estimate the extent of dialogue over different issues in several empirical and laboratory settings. In the current paper, we extend the logic of issue choice to the specific case of positive vs. negative campaign themes.

Geer (2006), in his detailed historical study of American Presidential campaigns, informally makes an argument similar in spirit to what has been modeled in this paper. While positive campaigns allow candidates to "talk past each other" and voters would "assume innocence unless proved guilty", negative campaigns carry the risk of being caught "making unsubstantiated charges" (Geer, 2006; page 51). We allow, in addition, the possibility that even negative campaigns, when carried on by both sides, may not reveal much information either.

1.1 Model: Brief Discussion

In our formal model, each of the two candidates has a privately known quality - either good or bad. At the beginning of the campaign, each candidate has the option to learn about the quality of the rival by investing a cost. Such costly learning captures a range of things from researching the rival candidate’s voting records and personal history to privately polling sections of the electorate in order to find out about how the public views the rival’s positions on salient issues. Armed with information about their own quality and possibly the rival’s quality, candidates commit to a campaign theme: positive or negative. Such precommitment is a simplifying assumption made in order to ignore the dynamic aspect of campaigns where a candidate make counter-claims in response to the rival’s claims, and is entirely standard in the literature on issue choice. In the model, we blackbox the actual process of voter opinion formation in what we call the information revelation protocol. If one candidate chooses a positive campaign and the other a negative one, we say that there is a fruitful debate, otherwise there is cross talk. In case of a fruitful debate, the candidate whose quality is discussed is said to be focal while the other candidate is non-focal. In case of cross-talk, both candidates are focal. In our benchmark case, we assume a deterministic information revelation protocol: a candidate’s true quality is revealed if only he is focal, and the campaign reveals no information about non-focal candidates. In a latter extension, we assume a probabilistic information revelation protocol: the quality of focal candidate is revealed with a higher probability than that of non-focal candidates. Voters vote based on information revealed through the protocol under consideration. All voters have the same preference and prefer to vote
for the good rather than the bad candidate.

Given the information revelation protocol, if a good candidate is facing a bad candidate, the former would prefer that either candidate be focal while the latter would prefer that neither is focal. This means that the two candidates have opposite preferences over message profiles: the good candidate prefers to go positive (negative) when the bad candidate goes negative (positive), and the bad candidate prefers to go positive (negative) when the good candidate goes positive (negative), leading to a matching pennies game between the good and bad types. Since the bad candidate wants to hide (conceal information) and the good candidate wants to chase (reveal information), we title the competitive process of information provision as a Hide and Seek game. The unique symmetric equilibrium outcome of this game describes candidate behavior and determines the extent of information revealed in electorate.

The introduction of uncertainty between candidates and the option of costly search is a crucial innovation in this paper. Between-candidate uncertainty captures a fundamental asymmetry between positive and negative campaigns that cannot be obtained in models which start out assuming that candidates know about each others’ type (e.g. PY). While information used in a positive campaign is free for a candidate, truth in a negative campaign is costly to him. As a consequence, positive campaigns contain more information than negative campaigns. Moreover, this feature allows us to explicitly distinguish between truthful negative campaigns and false attacks. However, it must be remembered that false attacks also play a vital role in information revelation: if a good candidate can reveal his type to the voter by defending himself successfully against false attacks.

1.2 Main Results

Because of incomplete information between candidates, the prior belief of a candidate being good plays a major role in determining the nature of debate. Using this prior as a proxy for average (expected) candidate quality, we focus on understanding the strategic behavior of candidates as a function of this average (expected) candidate quality and the welfare implications of such behavior. The model confirms the conventional wisdom that the incidence of negative advertising increases as the average quality worsens. However, the hide-and-seek nature of the race provides an advantage to the “rarer” type. In particular, a good candidate can most effectively reveal his type through positive advertising when the average candidate quality is low and there is a lot of negative campaigning. At the other extreme, when the average candidate quality is very high, all candidates engage in more positive campaigning: but this allows the bad candidates to effectively “hide” by avoiding debate with the good types. Thus, while an electorate with low expected candidate quality is competitive but efficient for the purpose of candidate selection, one with a high average quality is inefficient. Consequently, voter welfare in terms of the ex-post expected quality of the winning candidate may actually go down with an increase in the ex-ante expected
candidate quality.

The model also allows us to talk about a novel role of campaign resources. Snyder 1989, for example, examines the role of campaign resources in finding information about the opponent. The search cost can be seen as an index of the extent of asymmetry in information between the candidates. While a lowering of this cost improves the information content of negative advertising, we show that the bad type has a stronger incentive to engage in search than the good type. Therefore, the expected welfare of the voter is not monotonic in the cost of search. In particular, if a social planner could "select" the cost of search in order to maximize the probability of correct selection, then she would set the cost to zero when the good type is more common and set the cost very high when the bad type is more common. Similarly, the voter’s welfare is not monotonic in the payoff from winning office.

1.3 Related formal work

As mentioned before, the current paper brings together two strands of theoretical work on political campaigns: one on issue engagement and the other on positive vs. negative advertising. Simon (2002) presents a model where candidates allocate an advertising budget over many issues, and shows that each candidate has an incentive to emphasize a different set of issues rather than engaging in a dialogue with the rival on any given issue. According to Simon, a dialogue can be expected on an issue only if (i) it has overriding salience, (ii) mass media forces dialogue, or (iii) candidates behave “irrationally” for whatever reason. Kaplan et al (2006) introduces uncertainty about voter preferences over candidates’ positions and obtains dialogue in Simon’s model in a mixed strategy equilibrium. In our model, the between-candidate uncertainty performs a similar role as candidate uncertainty over voter preferences in Kaplan et al (2006) and leads to fruitful debate in equilibrium.

Earlier formal work on choice between positive and negative advertising (Skaperdas and Grofman 1995, Harrington and Hess 1996) takes as primitive an “influence function” that assumes that negative advertising reduces support both for its sponsor and target. Skaperdas and Grofman (1995) finds that the trailing candidate engages in more negative advertising than the frontrunner, and Harrington and Hess (1996) finds that the candidate with less attractive personal attribute runs a more negative campaign. In the equilibrium of our model too, the “bad” candidate is weakly more likely to engage in a negative campaign than the “good” candidate (and strictly so unless the prior expected candidate quality is very high).

PY considers a signaling model where candidates rationally choose the campaign theme and voters infer candidate quality by observing the chosen theme. The authors find that a candidate

\[ \text{2} \] Desposato (2008) studies the incidence of negative advertising in Latin American countries in a comparative perspective by using similar influence functions, but the outcome on voting probabilities is random.

\[ \text{3} \] Mattes (2008) is a very similar model with choice between informative advertising on two dimensions: negative vs. positive and issue vs. character.
uses a negative campaign when he either does not have too much to say about himself or he knows that his opponent is very bad. While these authors assume that negative advertising contains only hard information and is therefore always informative, our framework accounts for both “good” and “bad” motivations for attack by considering softer information. Consequently, these two models generate opposite empirical predictions about the effectiveness of negative advertising.

PY finds that in an environment where most candidates are expected to run negative campaigns, when a candidate runs a negative campaign against one running a positive campaign, the former is more likely to win. We obtain the exactly opposite conclusion: in such an environment, the positive campaigner has an advantage. In our model, when the expected candidate quality is very low, the bad types use negative campaigns to turn the focus on the rival - but this allows the rare good type the opportunity to create focality by running a positive campaign.

We also show that the full knowledge of rival type assumed in PY does not hold, even for very small search costs.

The remainder of the paper is organized as follows. Section 2 sets up the benchmark model in which the candidates are either “good” or “bad” and Section 3 characterizes the equilibrium. Section 4 discusses how candidate behavior in the benchmark case changes as the prior belief and the search cost change, and analyses welfare implications. Section 5 presents a few extensions and Section 6 concludes the main body of the paper. Appendix A discusses an extended version of the model with voter inference and a more general type space. Most proofs are in Appendix B.

2 Basic Model: Binary Types

There are two players: candidates 1 and 2 with a private quality \( \theta_i, (i = 1, 2) \) which can be either Good (\( G \)) and Bad (\( B \)).\(^4\) For both candidates, quality follows a commonly known Bernoulli distribution with the prior probability of a good type \( \alpha \in (0, 1) \). The candidates run campaigns (positive or negative) which reveal information to a voter about quality based on which she votes for one of the two. While the voter is not modeled explicitly as a player, her actions based on the revealed information are taken into account in the payoffs arising from candidate actions. In appendix A we show exactly the same conclusions hold when we formally model the voter as a player.

2.1 Actions

Player \( i \) has two different action choices: the campaign action \( M_i \in \{P, N\} \) and the search action \( X_i \in \{S, NS\} \). \( P \) denotes a positive campaign and \( N \) denotes a negative one. If player \( i \)

\(^4\)The “quality” of a candidate can be thought of in two ways. In a common values framework where all voters have the same preference, quality captures all characteristics that voters care about. In a private values framework where the two candidates can be assigned two locations on the left-right ideological continuum, quality can simply be thought of as the distance of a candidate from the median voter’s ideal point.
undertakes action $S$ (search), he gets to know the type of his rival $-i$ with certainty. If action $NS$ (no search) is taken, the rival’s type is not known. One can think of the search action as being taken before the campaign choice, so that the message can be conditioned on the information obtained through search. But we assume that the search action itself is private, i.e. a candidate cannot detect whether the rival has searched or not. Thus, the search stage and the debate stage can be considered simultaneous from the strategic point of view. Campaign choices by the candidates are also, in the same sense, strategically simultaneous: we assume that a candidate cannot condition his choice of campaign on the campaign chosen by the other candidate.\footnote{Since the campaign theme is part of the broader campaign strategy which is determined in advance (rather than tactics which can change as the campaign progresses), the simultaneity of message choice is not too bad an assumption to start with.} The campaign profile is denoted by $M = \{M_1, M_2\}$, the search profile by $X = \{X_1, X_2\}$ and the type profile by $\theta = \{\theta_1, \theta_2\}$. Campaigns are thought of as public debates. The payoff to player $i$ from an action and type profile $\{M, X, \theta\}$ is assumed to be the payoff $u_i(M, \theta)$ from debate less the cost of search, which is $c > 0$ if $X_i = S$ and zero otherwise. The payoff from debate $u_i(M, \theta)$ depends on the information revelation protocol. The winner of the debate gets a payoff $w > 0$, while the one who loses the debate gets a payoff of 0. We normalize $w = 2$.

The search cost $c$ is an index of how easy it is for a candidate to find out detailed information about the other candidate: in this sense it measures the extent of asymmetry of information between candidates. Since the payoff from winning the debate has been normalized, in effect, $c$ captures the ratio of the actual cost of search to the payoff from winning office. Thus, an increase in the importance of the contested office (with the difficulty of finding information about the rival remaining the same) would imply a drop in search cost. In the paper, we restrict $c$ to lie in the range $(0, \frac{1}{2})$. In this range, we show that search occurs in equilibrium for moderate values of the prior $\alpha \in (c, 1 - c)$. While the case with $c > \frac{1}{2}$ can easily be covered by the model, we do not formally study this case since there is no information acquisition for any prior belief over candidate quality in equilibrium (please see footnote 8).

2.2 Information Revelation Protocol

The campaign can be thought of as a public debate that reveals information to the voter. The actual process of debate is not modeled: we assume a protocol which determines how information about candidate types is revealed to the voter depending on the campaign profile. If one candidate goes positive and the other goes negative (i.e. $M_1 \neq M_2$), then the former candidate is focal in the sense that his quality is subject to a fruitful debate. If on the other hand, there is cross talk, i.e. if $M_1 = M_2$, there is no focal candidate. We assume that a focal candidate’s quality is revealed to the voter and a non-focal candidate’s quality is not.

A focal candidate wins the election if he is revealed to be good and loses the election if he is revealed to be bad. If there is cross talk, the winner is chosen randomly with equal probability.
Although simplistic, such a passive voter response to debate works for a two-type case because if one candidate is revealed to be good (bad), the other candidate cannot be better (worse). In Appendix A, we show that if we include the voter as a rational player in the game, such “passive” voting strategies considered here arise as equilibrium behavior, and the equilibrium remains unchanged.

Assume that the winner of the debate gets a payoff normalized to 2. In this constant sum game, the utility from debate $u_1(M, \theta)$ for player 1 is given by the following table, and that for player 2 is $u_2(M, \theta) = 2 - u_1(M, \theta)$.

$$
\begin{align*}
  u_1(P, P, \theta) &= u_1(N, N, \theta) = 1, \\
  u_1(P, N, G, \theta_2) &= u_1(N, P, \theta_1, B) = 2, \\
  u_1(P, N, B, \theta_2) &= u_1(N, P, \theta_1, G) = 0,
\end{align*}
$$

The rather extreme assumption that the media reveals the true type of the focal candidate and reveals nothing otherwise is not necessary for the qualitative results of the model to go through. It has been made for technical convenience so as to be able to drive the basic point home without using unnecessary parameters. In section 5 we discuss the results in a generalized model where this extreme assumption is relaxed retaining the assumption that a claim reveals information with a higher probability if it is faced with a counter-claim. In that section, we use a probabilistic (rather than deterministic) information revelation protocol which assumes that (1) in a fruitful debate, the quality of the focal candidate is revealed with a higher probability than the non-focal one, and (2) the probability that the voter learns neither candidate’s type is higher under cross talk than under a fruitful debate.

### 2.3 Incentives

To understand the incentives that such a payoff structure creates, it is useful to describe them in a normal form. There are three possible situations, depending on whether a good type faces a good type, a bad type faces another bad type, or whether the two candidates are of different types. Each case is described in a separate $2 \times 2$ matrix, with the row player’s payoff shown in the matrix.

<table>
<thead>
<tr>
<th>G-type</th>
<th>B-type</th>
<th>G-type</th>
<th>B-type</th>

<td>2</td>
<td></td>
<td>1</td>
</tr>
</tbody>
</table>

Suppose for now the candidates knew each other’s types. Then they would know which one of
the above three situations they were in. If a good candidate were facing another good candidate, then it is strictly dominant for both to run a positive campaign: both players would want to discuss their own qualities. If a bad candidate were facing another bad one, then it is strictly dominant to use a negative campaign: neither player wants the focus on himself. When a good candidate faces a bad candidate, there is a matching pennies game: the good candidate wants to reveal information about either candidate: thus he wants either to be focal himself \((P, N)\) or the rival to be focal \((N, P)\). The bad candidate, on the other hand, wants to conceal information by inducing cross talk \((P, P)\) or \((N, N)\). What makes this game interesting is that there is incomplete information about the rival’s type, and each candidate has an incentive to invest in research about the rival’s quality before deciding the campaign theme.

At this point, two comments are in order about some of the assumptions of the model.

In a formal sense, the campaign choice \(M_i\) by candidate \(i \in \{1, 2\}\) is a *message* about his private information \(\theta_i\). There are two traditions in economics about the relationship between messages and private information, and both have been applied to the analysis of political advertising. At one extreme, messages are thought to be cheap talk, i.e., completely unverifiable (Prat 2004). At the other extreme, messages are considered to be completely verifiable “signals” about private information, and therefore by definition truthful (PY). We recognize that while the content of candidate statements often carry valuable information about candidate types, such statements also include half-truths, unverifiable claims and outright lies. Even a fact-checking media may not always be able to ascertain the truth in all cases. We therefore assume that messages are only *conditionally verifiable*, i.e., \(\theta_i\) is revealed only when \(M_i = P\) and \(M_{-i} = N\). One interpretation could be that there is always two kinds of information about a candidate: positive information and negative information. Very often, both kinds of information have to be weighed against each other to have full picture of the quality of a candidate. Such a complete assessment cannot be obtained if both sides of the same issue are not debated by the candidates.

We assume that search by one candidate about the other’s quality is private. There are two restrictions embedded in this assumption. First, while deciding on the campaign theme, a candidate does not know whether his rival has found the relevant information to ascertain his quality. Second, when there is a fruitful debate, the voting public cannot distinguish whether the negative facts about the focal candidate were unearthed by the media or the rival candidate or were simply revealed through the process of debate. See footnote 9 for how the results would change when search is still a costly option, but a candidate is aware of whether the rival searched or not.
3 Equilibrium and its properties

Each candidate has to decide whether to acquire information and to choose a campaign theme conditional on the information acquired (if any). Since a strategy for a player is a map from types to probabilities of each action, the strategy set for a candidate of type $\theta$ should include the following three elements:

1. $p(\theta)$ : probability of search.

2. $q(\theta)$ : probability of using a positive campaign ($P$) conditional on not searching

3. $r(\theta, \theta')$ : probability of using a positive campaign ($P$) conditional on searching, and discovering the rival candidate to be of type $\theta'$

The equilibrium concept considered here is Bayesian Nash equilibrium where candidates engage in type-symmetric strategies. Since the equilibrium strategies depend only on the types and not on the identities of players, the strategies are not indexed by the identity $i$ of the player. There are, of course, multiple equilibria of this model where candidate strategies depend on their identities. However, such equilibria require us to take an ad-hoc stand on which one among those is going to be focal. Since we are interested in a theory of “focality” of candidates anyway, we do not want to assume exogenously that one or the other asymmetric equilibria will be focal. We want focality of candidates to be generated endogenously from quality differences in an otherwise symmetric setting.

From the previous discussion, we must have $r(G, G) = 1$ and $r(B, B) = 0$ (strictly dominant strategies). The remaining elements in the strategy set of a player is the set of probabilities $p(G)$, $p(B)$, $q(G)$, $q(B)$, $r(G)$ and $r(B)$ where, with a slight abuse of notation, $r(G)$ denotes $r(G, G)$ and $r(B)$ denotes $r(B, G)$.

It is useful to define $\theta P \theta'$ as the probability of the event that when the two candidates facing each other are of types $\theta$ and $\theta'$ respectively, the candidate with type $\theta$ uses a positive campaign. Therefore:

$$\theta P \theta' = p(\theta)r(\theta, \theta') + (1 - p(\theta))q(\theta), \text{ where } \theta, \theta' = G, B$$

(1)

Expanding on equation (1), we define:

$$BPG = p_B r_B + (1 - p_B)q_B$$

$$GPB = p_G r_G + (1 - p_G)q_G$$

(2)

Lemma 1, which deals with campaign choice for each type of candidate conditional on available information, brings out the hide and seek nature of the game.
Lemma 1 For \( \theta \in \{G, B\} \), the campaign choice \( q(\theta) \) conditional on not searching, and the campaign choice \( r(\theta) \) conditional on finding the rival type to be different from own type, is determined as follows:

(a) On finding the rival to be a bad type, the good type uses a positive campaign \( (r(G) = 1) \) if \( BPG < \frac{1}{2} \) and a negative campaign \( (r(G) = 0) \) if \( BPG > \frac{1}{2} \). Conditional on not searching, the good type employs a positive campaign \( (q(G) = 1) \) if \( \Pr(B) \cdot BPG < \frac{1}{2} \) and a negative campaign \( (q(G) = 0) \) if \( \Pr(B) \cdot BPG > \frac{1}{2} \), where \( \Pr(B) = 1 - \alpha \).

(b) On finding the rival to be a good type, the bad type uses a positive campaign \( (r(B) = 1) \) if \( GPB > \frac{1}{2} \) and a negative campaign \( (r(B) = 0) \) if \( GPB < \frac{1}{2} \). Conditional on not searching, the bad type employs a positive campaign \( (q(B) = 1) \) if \( \Pr(G) \cdot GPB > \frac{1}{2} \) and a negative campaign \( (q(B) = 0) \) if \( \Pr(G) \cdot GPB < \frac{1}{2} \), where \( \Pr(G) = \alpha \).

Proof. See Appendix B. □

According to Lemma 1, the campaign choice of a good type depends only on \( BPG \), the probability with which she expects a bad type of the rival to employ the positive campaign against her. If the bad type goes positive with a high probability, the good type prefers to go negative and expose the bad type, and if the bad type goes negative with a high probability, the good type prefers to go positive and reveal her true type. In the same way, the message of the bad type depends only on \( GPB \), the probability that the good type of the rival uses a positive campaign against him. The bad type always prefers to avert a fruitful debate with the good type, and therefore tries to mimic her campaign choice. As an implication of Lemma 1 part (a), conditional on not searching, the good type has a strictly dominant campaign choice \( (P) \) if it is the more common type. Similarly, Lemma 1 part (b) implies that conditional on not searching, the bad type finds it strictly dominant to choose a negative campaign \( (N) \) if the bad type is more common. In other words,

\[
\alpha > \frac{1}{2} \Rightarrow q(G) = 1 \\
\alpha < \frac{1}{2} \Rightarrow q(B) = 0 
\]

(3)

Proposition 1 demonstrates the equilibrium behavior of candidates.

Proposition 1 The unique equilibrium for different values of the prior is as follows:

(i) If \( \alpha < c \), there is a fully separating equilibrium where no type searches, the good type uses the positive campaign and the bad type attacks i.e. \( p(G) = p(B) = 0, q(G) = 1, q(B) = 0 \), and (off equilibrium), \( r(G) = r(B) = 1 \).

\textsuperscript{6}We do not consider the case \( \alpha = c \) since it is non-generic. In this case, we can have a continuum of equilibria. However, the equilibria discussed in the proposition extended to \( c \to \alpha \) still exist in the limit \( c = \alpha \). The case of \( \alpha = 1 - c \) is not considered due to the same reasons.
(ii) If $\alpha \in (c, 1 - c)$, there is a partially separating equilibrium where both types search with positive probability, i.e. $p(G) = \frac{1}{2}(1 - \frac{c}{\alpha})$, $p(B) = \frac{1}{2}(1 + \frac{c}{1-\alpha})$. The good type employs a positive campaign when she does not search and a negative campaign when she searches and finds the rival to be a bad type, i.e. $q(G) = 1$, and $r(G) = 0$. The bad type employs a negative campaign when he does not search and a positive campaign when he searches and finds the rival to be a good type, i.e. $q(B) = 0$ and $r(B) = 1$.

(iii) If $\alpha > 1 - c$ there is a fully pooling equilibrium where both types send the positive campaign and neither type searches, i.e. $p(G) = p(B) = 0$, $q(G) = q(B) = 1$, and (off equilibrium), $r(G) = 0$, $r(B) = 1$.

Proof. See appendix B. ■

If either type is too rare (when $\alpha < c$ or $\alpha > 1 - c$), then there is no incentive for search, and each candidate acts as if the rival is of the common type. When $\alpha < c$, the bad type finds it strictly dominant to employ a negative campaign (by equation (3)). Since is no search, the action of the bad type is predictable, i.e. $B = 0$, and by Lemma 1 part (a), the good type employs a positive campaign. Thus, when expected candidate quality is very low, we have a “competitive” electorate, there is a lot of negative advertising, but the good type can always separate itself from the bad type by ensuring a fruitful debate. At the other extreme, when $\alpha > 1 - c$, the good type always goes positive (equation (3)), and Lemma 1 part (b) dictates that then the bad type will use a positive campaign too, and successfully ensure cross talk. Therefore, when the expected candidate quality is very high, we have a “conservative” electorate, where there is only positive advertising, and it is impossible to distinguish the good type from the bad. Notice that the no-search case demonstrates that the rarer type has the advantage in the hide-and-seek game.7

Search is undertaken only when neither type is very rare, i.e., the expected candidate quality is moderate ($c < \alpha < 1 - c$). The good candidate always provides arguments supporting himself (positive campaign) unless he is sure that the rival is a bad type, in which case he tries to expose the rival by going negative. The bad candidate on the other hand has a default campaign which is negative, but when he is sure that the rival is a good type, he tries to ensure cross talk by defending himself (positive campaign), hoping that the rival has not searched and is going to employ a positive campaign too. This equilibrium is supported by the fact that the good candidate searches less frequently than the bad type.

To see the technical intuition for the equilibrium with search, notice that if a candidate were to invest in search with any positive probability, he must play different actions with different types of the rival. Since the good type plays $P$ if the rival is also good, he must play $N$ when search reveals the rival to be bad, i.e. $r(G) = 0$. In the hide-and-seek game with the bad type, the good type plays

\[ r(B) = 1. \]

7If $c > \frac{1}{2}$, then we have either $\alpha < c$ or $1 - \alpha < c$. Whenever $c > \frac{1}{2}$, there is no search. For $\alpha < \frac{1}{2}$, the equilibrium is fully separating with the good type going positive and the bad type going negative; and for $\alpha > \frac{1}{2}$, the equilibrium is fully pooling with both types going positive.
does not want to play the same action against the bad type all the time. Hence, the good type uses \( P \) conditional on not searching and \( N \) conditional on searching and discovering the rival to be bad. Similarly, the bad type has \( r(B) = 1 \) and \( q(B) = 0 \). The search probabilities are chosen by each type so as to keep the “other” type indifferent between searching and not searching: search thus performs the role of mixing between the two different actions in the debate.

As demonstrated by the above proposition, irrespective of whether search occurs or not, when two good candidates are in competition, there is cross talk with both candidates arguing in support of themselves (positive campaign). When two bad candidates face each other, we again have cross talk, but with negative campaigns if \( \alpha < 1 - c \) and with positive campaigns otherwise. A fruitful debate can occur only between a good and a bad type.

Notice that although we have considered “mechanistic” or passive voting, including the voter as a rational player does not alter this equilibrium. First, note there is nothing more to learn from cross-talk because both candidates take the same action. As long as there is a common prior over both candidates, it is rational for the voter to randomly choose the winner. In equilibrium, fruitful debate occurs only between two different types of candidates - thus the passive action is again rational. We make the additional assumption that off the equilibrium, if the voter observes a candidate to be of a type that is not supposed to be observed in equilibrium (e.g. type \( B \) in the case \( \alpha < c \)), then the voter assumes that each type of the rival candidate has a small (not necessarily equal) positive probability of having played \( N \), which implies that there remains an uncertainty about the type of the rival. Thus, off the equilibrium path too, the voter strictly prefers to vote for the candidate revealed to be good and against the candidate revealed to be bad. Therefore, the “naive” voting action hardwired in the payoffs does not change if we include a rational voter in the model. Voter inference is formally discussed in Appendix A.

### 3.1 Properties of Search

A few properties of search are worth mentioning here:

1. Given the equilibrium campaign strategies, search has the property of *strategic substitutability*: certain search by one type takes away the incentive of the other type to search. Moreover, the type that does not search can mix messages in such a way as to nullify the informational advantage of the type that has searched. Therefore, no candidate searches with certainty, even if search cost is very low. The result that search must be probabilistic casts doubt over the assumption of full information between candidates which is assumed in PY.\(^8\)

\(^8\)The result that search is always probabilistic depends on the assumption that search is private. In a model where each candidate knows whether the rival has searched or not and can make their campaign choice conditional on such information, search is never probabilistic: for all parameter values in a type-symmetric equilibrium, a given type either searches or does not search. Mixing happens at the level of campaign choice.
2. Search is reciprocal, i.e. if one type searches with a positive probability, the other type does so too.

3. If search occurs, the bad type searches with a higher frequency than the good type. In the equilibrium with search, we must have $p(B) > \frac{1}{2} > p(G)$. Notice that the ex-ante marginal value of positive advertising is higher to the good type than the bad. It is this advantage that depresses the good type’s incentive to search, and raises the bad type’s motivation for the same. The cost of search drives a wedge between the incentives to search of the two types: For any given $\alpha$ for which search is worthwhile in equilibrium, $p(B) - \frac{1}{2}$ and $\frac{1}{2} - p(G)$ are both increasing in $c$: This leads to an inefficiency which we discuss later in the discussion on candidate selection. To drive the point home further, note that as $c \to 0$, both $p(B)$ and $p(G)$ converge to $\frac{1}{2}$ and the inefficiency due to search vanishes in the limit.

3.2 Campaigns and candidate quality

There is a large empirical/experimental literature discussing the effect of negative advertising. The main finding is that attack advertising hurts both the sponsor and the target of the negative campaign, although there is considerable disagreement on the relative and absolute size of these effects. Recent formal work by PY and Mattes (2008) has provided a theoretical foundation for these effects by studying voter inference of candidate qualities from their campaign strategies. The most important issue highlighted in this paper is that information about candidate quality is revealed by the profile of campaign choices rather than the choice by an individual candidate: A negative campaign may have very different effects depending on whether it is met by a positive or a negative campaign.

3.2.1 Campaign profiles and Information Revelation

The profile of campaigns reveal information to the voter directly through the information revelation protocol, and additionally through equilibrium inferences. To analyze voter inference, one really has to look at the voter as a rational player. We have informally discussed before and formally demonstrated in appendix A that the equilibrium strategies derived earlier in this section can be used to analyze voter inference of candidate types from campaign choices.

A fruitful debate reveals the true quality of the focal candidate. Moreover, the rival candidate’s type can also be inferred with certainty by the rational voters. In equilibrium, a fruitful debate can occur only between opposite types: such a debate has either a good candidate “exposing” a bad one, or a good candidate successfully defending herself against attacks by a bad one.

In case of cross talk, there is no new information revealed directly through debate. In equilibrium, voters cannot distinguish between the two candidates as they are observed to take the same action. However, we can talk about the effect of campaign choice in terms of whether the prior,
i.e., expected candidate quality is updated upwards or downwards. When there is cross talk with positive campaigns, either or both of the candidates must be good. On the other hand, when both candidates use negative campaigns, at least one of the two candidates must be bad, and voters adjust their assessment downwards. This feature of equilibrium leads to voter inferences under cross talk discussed below.

Formally, suppose both candidates choose the same campaign \( M_1 = M_2 = M \in \{P, N\} \), and the inferred probability of the candidates being good is \( \hat{\alpha}(M) \). Then,

1. If \( \alpha \in (c, 1 - c) \), then \( \hat{\alpha}(N) < \min\{\alpha, \frac{1}{2}\} \) i.e., when both candidates employ negative campaigns, the assessment of candidate quality goes down. In fact, irrespective of the prior \( \alpha \), the voters believe that both the candidates are more likely to be bad than good. The opposite conclusions hold when each candidate runs a positive campaign, i.e., \( \hat{\alpha}(P) > \max\{\alpha, \frac{1}{2}\} \).

2. If \( \alpha > 1 - c \) there is full pooling: the campaign choice is completely uninformative about quality, and thus \( \hat{\alpha}(P) = \alpha \).

3. If \( \alpha < c \), we have full separation. Then, anyone using a positive campaign distinguishes himself as a good type while anyone attacking the rival in debate reveals himself to be a bad type. Formally, in this case, \( \hat{\alpha}(N) = 0 \).

### 3.2.2 Effect of Negative Advertising

In order to compare our results directly with the existing literature on negative campaigns, we now turn to the following question: Suppose a candidate is observed to run a negative campaign. What effect does our model predict about the sponsor and the target? The answer, in our model, depends on what campaign the target is observed to run. If the rival also goes negative, the expected quality of both the target and the sponsor goes down. On the other hand, if the rival runs a positive campaign, the quality assessment of the sponsor of the negative campaign and that of the target move in opposite directions.

For the case of a fruitful debate (unmatched messages), there are two cases to consider. When \( \alpha < c \), only the bad type runs a negative campaign: Thus the sponsor of a negative campaign is hurt and the target benefits. When \( \alpha \in (c, 1 - c) \), the effect is ambiguous since both good and bad types run negative campaigns. In particular, the attacker in a fruitful debate is revealed to be good with probability \( q(\alpha) \) and bad with probability \( 1 - q(\alpha) \), where

\[
q(\alpha) = \frac{p_G p_B}{P_G p_B + (1 - p_G)(1 - p_B)}
\]

It can be checked that \( q(\alpha) > \frac{1}{2} \) if and only if \( \alpha > \frac{1}{2} \). Remark 1 sums up the effect of a negative campaign when the rival uses a positive campaign in equilibrium.
Remark 1 Suppose in equilibrium, one candidate runs a negative campaign and the rival runs a positive campaign. The negative campaigner is more likely to win than lose (and the positive campaigner is more likely to lose than win) if and only if the bad type is rarer, i.e., $\alpha > \frac{1}{2}$.

Later, we observe in remark 2 that when $\alpha < \frac{1}{2}$, a random candidate is more likely to run a negative campaign and when $\alpha > \frac{1}{2}$, he is more likely to run a positive campaign. Therefore, when a negative campaign is faced with a positive one, the attacker has the advantage if most candidates are expected to run positive campaigns and the attacker has a disadvantage if most candidates are expected to go negative. In other words, the candidate using the less expected mode of campaign has the advantage. PY (Proposition 4) has the opposite finding: when two candidates choose “unmatched” messages, the one using the dominant mode of campaigning is at an advantage. The main reason for the difference is that while PY consider only informative campaigns, we consider softer information that leads to a hide-and-seek framework.

4 Comparative Statics

In this section, we examine the comparative static properties of the equilibrium for different levels of the search cost and average candidate quality, and discuss the implications of such properties.

4.1 Welfare Analysis: Candidate Selection

Looking at political campaigns as debates between candidates with partial information about each other helps us understand a few important issues about the efficiency of the campaign process especially in terms of its ability to select the better candidate. The major finding of the model is that as the prior probability of a candidate being good increases, the probability of a good candidate being selected through the electoral process may actually go down. Figure 1 plots the total probability of selection of the good candidate against the prior $\alpha$ for some given search cost $c^9$. In the graph, there exist downward jumps in otherwise piecewise continuous and monotonically increasing graphs. There are three regimes based on ranges of $\alpha$: Full separation, partial separation and full pooling, and the downwards jumps occur when we move from a more efficient regime to a less efficient one as the average candidate quality increases. Note also that since an increase in the search cost favours the bad type, the downward jumps are larger as the cost of information increases.

\begin{enumerate}
\item Denote the total probability of selection of the good type given $c$ and $\alpha$ as $f_c(\alpha)$. It can be deduced from Propositions 1 that:
\end{enumerate}

\begin{align*}
f_c(\alpha) &= \begin{cases} 
2\alpha - \alpha^2 & \text{if } \alpha < c \\
\frac{3}{2} \alpha - \frac{1}{2} \alpha^2 - \frac{1}{2} c^2 & \text{if } c < \alpha < 1 - c \\
\alpha & \text{if } \alpha > 1 - c
\end{cases}
\end{align*}
The total probability of selection may not fully reflect the efficiency of debate as a selection mechanism. Perhaps a better indicator of the efficiency of debates in selecting the right candidate would be a measure of how often the good candidate wins when competing against a bad candidate. Hence we look at the equilibrium probability of a fruitful debate conditional on candidates being of different types. Denote this probability \( \beta(\alpha, c) \). Proposition 2 shows how \( \beta \) changes with the parameters of the model.

**Proposition 2** Suppose one of the two competing candidates is a good type and the other is a bad type. Debate is always fruitful if \( \alpha < c \), never fruitful if \( \alpha > 1 - c \), and if \( \alpha \in (c, 1 - c) \) debate is fruitful with a probability \( \beta(\alpha, c) = \frac{1}{2} - \frac{c^2}{2\alpha(1-\alpha)} \).

**Proof.** Follows from proposition 1. ■

When there is no search, the rarer type has full advantage in the hide and seek game. For very low priors, debate is fully efficient and for very high priors, debate is fully inefficient. When the prior is moderate, both types search in equilibrium.

In the case when the search cost is very low, i.e. \( c \to 0 \), we have \( p_B \) and \( p_G \) both converging to \( \frac{1}{2} \). In this case, the debate between the good and bad types reduces to the matching pennies game in which there is no advantage to either type: hence each message profile occurs with equal probability. Then \( \beta(\alpha, c) \to \frac{1}{2} \) for almost all values of the prior. As the search cost increases, there is a further inefficiency due to differential incentives for search that the two types have. As mentioned before, we have \( p_G < \frac{1}{2} < p_B \); moreover, both \( |p_G - \frac{1}{2}| \) and \( |p_B - \frac{1}{2}| \) are increasing in \( c \).
This inefficiency due to differential incentives for search leads to a further welfare loss of \( \frac{c^2}{2\alpha(1-\alpha)} \). Figure 2 shows how \( \beta(\alpha, c) \) changes for different values of \( \alpha \). The dashed line shows \( \beta \) when \( c \to 0 \).

![Figure 2: Probability of correct selection when two candidates are of different types](image)

Given an expected candidate quality \( \alpha \), if a social planner could choose the search cost \( c \) (or more realistically, the extent of office perks), what would the best choice be? The answer depends on whether the good or the bad type is more common.

If \( \alpha > \frac{1}{2} \), we unambiguously improve welfare by reducing \( c \), and the best choice of \( c \) would be as close to zero as possible. On the other hand, if the bad type is more common, there are two opposing effects. When \( c < \alpha \), a marginal reduction in \( c \) reduces the inefficiency due to search and increases \( \beta \). On the other hand, for any given \( \alpha \) less than \( \frac{1}{2} \), if we set \( c > \alpha \), we get full separation of types. Hence, if the bad type is more common, a social planner can achieve full separation by sufficiently reducing the prize from office.

### 4.2 Negative Advertising

Next, we look at the type of messages exchanged in the debate as the prior varies. As the average candidate quality improves, the ex-ante probability that a candidate will employ a negative campaign goes down. In general, the bad type’s propensity to attack goes down as the probability of the rival being good goes up. For moderate values of the prior, the propensity of negative campaigning decreases with \( \alpha \) because the good type’s increasing aggressiveness (in searching and attacking the bad type) is more than compensated by the bad type’s increasing conservatism (in searching and sending positive messages). This is illustrated in figure 3 and stated in Remark 2,
which follows from Proposition 1.\textsuperscript{10}

![Figure 3: Probability of a negative campaign as a function of the prior](image)

**Remark 2** The probability of negative advertising is strictly decreasing in the prior for $\alpha < 1 - c$ and is equal to 0 for $\alpha > 1 - c$. Negative advertising is more frequent than positive advertising if the bad type is more common, and less frequent if the good type is more common.

At this stage, one may want to distinguish between a negative campaign targeted against a bad type from an attack on a good type, presumably because the latter is likely to be less truthful than the former. In this model, a good candidate never wages a negative campaign against a good candidate. A good candidate is subjected to a negative campaign only by a bad candidate that has not searched.

Just like negative advertising as a whole, the incidence of negative advertising targeted against a good type goes down as the prior improves.\textsuperscript{11} The probability of attacks on the good type decreases with improvement in expected candidate quality because the bad type becomes less common and also starts searching more often. As the expected candidate quality improves, a growing share of negative advertising is informed attacks by the good type. In this sense, the share of truth in negative campaigns goes up as the expected candidate quality improves. Therefore, we have a “cleaner” electorate as the prior increases. However, this also implies that there is less information revelation through debate and as shown before, the selection performance worsens.

\textsuperscript{10}The probability of a negative message $\gamma(\alpha, c)$ is: $\gamma(\alpha, c) = \begin{cases} 
1 - \alpha & \text{if } \alpha < c \\
(1 - \alpha) - \frac{c}{2}(1 - 2\alpha) & \text{if } \alpha \in (c, 1 - c) \\
0 & \text{if } \alpha > 1 - c 
\end{cases}$

\textsuperscript{11}The probability of attack on a good type is $1 - \alpha$ for $\alpha < c$, $\frac{1}{2}(1 - \alpha) - \frac{c}{2}$ if $\alpha \in (c, 1 - c)$ and 0 if $\alpha > 1 - c$. 

20
5 Extensions

Although the hide and seek framework discussed in the paper is very simple, it can serve as a legitimate model of electoral competition. This framework can be extended to discuss several features necessary for a richer model of politics.

5.1 Probabilistic Information Revelation

Consider a generalization of the model discussed in section 2 and 3 where the quality of the candidate is revealed to the voter with a probability dependent on the profile of campaigns employed. Suppose the revelation of a candidate’s quality is a Bernoulli random variable distributed independently conditional on the campaign profile. If both candidates use positive advertising, each candidate’s quality is revealed to the voter with probability \( \phi_P \), and similarly, with probability \( \phi_N \) if both engage in negative advertising. If, on the other hand, one candidate employs a positive campaign and the other a negative campaign, then the focal candidate’s type is revealed with probability \( \pi_P \) and the non-focal candidate’s type with probability \( \pi_N \). we call this structure the "probabilistic information revelation protocol". we make two assumptions on the parameters:

\[
\begin{align*}
(A1) & \quad 1 \geq \pi_P > \pi_N \geq 0 \\
(A2) & \quad (1 - \pi_P)(1 - \pi_N) < \min\{(1 - \phi_P)^2, (1 - \phi_N)^2]\end{align*}
\]

(A1) captures the fact that in a fruitful debate, the quality of a focal candidate is revealed with a higher probability than that of the non-focal candidate, and (A2) says that the probability that the voter learns nothing is lower in a fruitful debate than in cross talk.\(^\text{
12}\) First, we demonstrate that under a probabilistic information revelation protocol, these two assumptions preserve the incentive structure in the basic framework.

If the types of both candidates are revealed, the voter compares the two and decides. If only one type is revealed, the voter votes for the candidate if he is revealed to be good and against him if he is revealed to be bad. If neither type is revealed, the voter votes randomly. In the notation used in section 2, the payoff to the candidates from each campaign profile when the two candidates

\(^\text{12}\) Notice that even if we let \( \pi_N = 0 \), a simple comparison of \( \pi_P \) and \( \phi_P \) (or \( \phi_N \)) will not allow us to compare the amount of information revealed in a fruitful debate with that in cross talk. The reason is that while in a cross talk, each candidate’s quality is revealed with probability \( \phi_P \) (or \( \phi_N \)) independently, \( \pi_P \) is the revelation probability only for the focal candidate.
are of the same type are as follows:

<table>
<thead>
<tr>
<th>G-type</th>
<th></th>
<th>B-type</th>
</tr>
</thead>
<tbody>
<tr>
<td>P</td>
<td>P</td>
<td>P</td>
</tr>
<tr>
<td>l</td>
<td>k</td>
<td>l</td>
</tr>
<tr>
<td>(2-k)</td>
<td>1</td>
<td>(2-m)</td>
</tr>
<tr>
<td>n</td>
<td>1</td>
<td>1</td>
</tr>
</tbody>
</table>

where \( k = \pi_P\pi_N + (1-\pi_P)(1-\pi_N) + 2\pi_P(1-\pi_N) = 1 + (\pi_P-\pi_N) \), and similarly, \( m = 1 - (\pi_P-\pi_N) \).

Notice that assumption (A1) implies (and is implied by) \( 1 < k \leq 2 \) and \( 0 < m \leq 1 \). This ensures that when a good type meets another good type, both find it strictly dominant to use positive advertising; and when a bad type meets another bad type, both find it strictly dominant to use negative campaigning. Next, consider the game between a good type and a bad type, where we can find the payoffs in the individual cells through a little algebra.

\[
\begin{align*}
\text{B-type} & \quad \text{G-type} \\
| & | & P & N \\
| & a_1 & b & | \\
| & b & a_2 & |
\end{align*}
\]

where

\[
\begin{align*}
a_1 &= 2 - (1 - \phi_P)^2 \\
a_2 &= 2 - (1 - \phi_N)^2 \\
b &= 2 - (1 - \pi_P)(1 - \pi_N)
\end{align*}
\]

Assumption (A2) is equivalent to \( b > \max(a_1, a_2) \), which induces the matching pennies structure. Therefore, when a good type faces a bad type, the former prefers fruitful debate (unmatched messages) and the latter prefers cross talk (matched messages).

The following proposition describes the equilibrium in the probabilistic revelation case. Under two additional restrictions, the features of the equilibrium are exactly the same as those in the deterministic revelation case. Denoting \( \pi_p - \pi_N \) by \( \pi \), we need (i) \( c < \frac{(b-a_1)^2}{(b-a_1)+\pi} \) and (ii) \( b-a_1 < \pi \). The first restriction simply requires the cost of information acquisition to be small enough, and the second one requires that under fruitful debate, the probability of the revelation of the focal candidate’s type is sufficiently higher than the probability of revelation of the non-focal candidate’s type. The second restriction is always satisfied if we assume that \( \pi_N = 0 \), i.e., a fruitful debate reveals information about the focal candidate only, and not about the non-focal candidate. With these two restrictions, proposition 1 is a special case of proposition 4.

**Proposition 3** Assume (A1), (A2), \( c < \frac{(b-a_1)^2}{(b-a_1)+\pi} \) and \( b-a_1 < \pi \). The following is the equilibrium for different values of the prior \( \alpha \):

(i) If \( \alpha < \min \left( \frac{c}{b-a_1}, \frac{1}{2} \right) \) there is a fully separating equilibrium with no search, i.e. \( p(G) = \)
\[ p(B) = 0, \quad q(G) = 1, \quad q(B) = 0, \quad \text{and (off equilibrium)}, \quad r(G) = r(B) = 1. \]

(ii) If \( \frac{c}{b-a_1} < \frac{1}{2} \), then for \( \alpha \in (\frac{c}{b-a_1}, 1 - \frac{c}{b-a_1}) \), there is a partially separating equilibrium where both types search with positive probability, and \( q(G) = 1, \quad r(G) = 0, \quad q(B) = 0, \quad r(B) = 1 \).

\[ p(G) = \frac{1}{2b-(a_1+a_2)} \left[ (b-a_1) - \frac{c}{\alpha} \right], \quad \text{and} \quad p(B) = \frac{1}{2b-(a_1+a_2)} \left[(b-a_2) + \frac{c}{1-\alpha} \right]. \]

(iii) If \( \alpha > \max \left( 1 - \frac{c}{b-a_1}, \frac{1}{2} \right) \) there is a fully pooling equilibrium on the positive message and neither type searches, i.e. \( p(G) = p(B) = 0, \quad q(G) = q(B) = 1, \quad \text{and (off equilibrium)}, \quad r(G) = 0, \quad r(B) = 1. \)

The proof of the proposition is provided in Appendix B. We note here that for the probabilistic information revelation model, the assumption of “passive” voting is no longer innocuous: We need to assume that voter inference is based only on the arguments made in the campaign and not additionally on guessing the strategic motivations of candidates for making particular campaign choices.

5.2 Continuous Type Space

With the deterministic information revelation protocol, we have a natural extension of our model to the continuous type case. To discuss the continuous type extension we need to formally include the voter as a third player in the game and discuss his beliefs given candidate strategies and revealed information. In Appendix A, we discuss voter beliefs and then show that there exists a class of equilibria in the continuous type case which is of the following kind: There is a cut-off quality \( \theta^* \) such that candidates with their type above the cut-off behave like the good type in the discrete model, and those with type below the cut-off behave like the bad type. There is a continuum of such equilibria, with the cut off \( \theta^* \) can take any value in a given interval. In this equilibrium, all results in the discrete model carry over. Moreover, we get an endogenous classification of the continuum of quality into “good” and “bad”, dictated by voter beliefs.

The continuous type extension is not of mere technical interest. It provides a comparison with the existing literature on adverse selection with one principal (the median voter) and two competing agents (the candidates). Banks (1990) analyzes Downsian competition where candidates may make false announcements about their preferred positions, but lying has an exogenous cost that increases in the distance between their preferred and announced positions. While Banks finds pooling of candidate types over an interval containing the median voter’s best point, Callander and Wilkie (2007) show that if there is a cheap talking type in the model, pooling happens at two disjoint intervals on either side of the median voter’s best point. Thus, the "best" types (those that are preferred most by the median voter) pool in the former paper while the "moderate" types pool in the latter, and all the other types separate. The continuous type space in this model can be interpreted as a space of possible candidate locations on the Hotelling line, with higher
quality implying a location closer to the median voter’s ideal point. In the equilibrium in the current model there are two clusters of pooling - one for the "good" types and the other for the "bad" types. The message in this paper is that if competition reveals information about only one candidate, it is possible to separate the good set of types from the bad set of types (where good and bad types are defined endogenously), but one cannot separate within the good or bad set of types.

It is important to note that there are multiple symmetric equilibria in the continuous type model. We use two refinement criteria: (i) better types must obtain weakly higher expected payoff in equilibrium and (ii) all types are revealed with positive probability in equilibrium. The first criterion is also used in PY, in a stronger form. The second criterion ensures that off-equilibrium beliefs about types play no role in equilibrium behavior. The class of equilibria we identify is the only one satisfying both these refinements and an additional technical restriction.

5.3 Uninformative Campaigns

In the paper, we have only allowed a candidate the choice to run a campaign about one of two issues: own quality (positive campaign) or the rival’s quality (negative campaign). Information is revealed if and only if both candidates focus on the same issue. One might legitimately ask whether our results would change if a candidate could run a “null campaign” in which he makes statements that are informative about neither candidate’s quality irrespective of whether it is faced with a positive or a negative campaign. In other words, a “null campaign” would allow a candidate to ensure cross-talk unilaterally. However, voter rationality in our model would prevent either candidate from running such a campaign.

Notice that for a good type, a positive campaign cannot do any worse than a null campaign irrespective of what the other candidate does: A positive campaign will either reveal no information or reveal the candidate as a good type, while the null campaign always blocks information revelation. Therefore, in any equilibrium where a candidate does not employ a weakly dominated action, a good type will never employ a null campaign. In such an equilibrium, if a candidate is seen to be running a null campaign, he is “outed” as the bad type with certainty. Therefore, it is not in the interest of the bad type either to run a null campaign. Our result implies that while candidates may often use uninformative messages, a whole campaign that is composed only of uninformative statements should not be observed in the real world.

---

13 We thank an anonymous referee for suggesting this extension.
14 More formally, in the game with a rational voter where null campaigns are allowed, the outcome in the equilibrium identified in proposition 4 continues to hold, and it is the only equilibrium if we additionally restrict candidates from playing weakly dominated strategies in equilibrium.
5.4 Conclusion

This paper examines the choice between positive and negative campaigns as a particular case of the more general decision problem of contradicting the opponent’s argument (revealing information through fruitful debate) and raising a different subject (concealing information through cross talk). The fundamental idea of the paper is that information transmitted in a debate is conditionally verifiable: the truth of an argument is more transparent when compared with a counter-argument. Previous formal theoretic work on positive vs. negative advertising has considered only truthful statements in advertising. Our model incorporates softer information as part of possible messages spoken in advertising campaigns. The model points out that a lie or ad hominem attack, while useless to the voter, might be useful to the candidate in “muddling” the debate and thus distracting the attention of the electorate. The model also shows that, contrary to popular perception, voter welfare is not monotonic in the expected candidate quality.

The existing body of empirical and experimental work investigating the role of attack messages has largely proved inconclusive in establishing whether such messages are beneficial or harmful. The current paper suggests that perhaps efforts to classify negative campaigns in such exclusive categories might be misdirected. We present a more nuanced picture in which negative campaigns may sometimes be useful and sometimes not-so-useful to the voter, depending on the motivation of the candidate running the campaign. We point out the information is often revealed jointly by the two candidates discussing two sides of the same issue - and for future work, we might need to take into account the entire profile of messages in order to set up the right hypotheses to test with field or laboratory data.

7 Appendix A : Rational voter model

In the main body of the paper, the voter is treated as "passive". In this section, we include a rationally updating voter and a more general space of types.

Consider a game $G(\Theta, F, c)$ with a voter and two candidates $i = 1, 2$. Each candidate has a private quality type $\theta_i$ that is drawn from a common type space $\Theta \subset R$ according to a common distribution $F(\cdot)$. The action space of candidates $i = 1, 2$ is exactly the same as specified in Section 2. Formally, this is a three stage game. In stage 1, the candidates observe their own realized type
and choose search action $X$ privately. In stage 2, the candidates play debate action $M \in \{P, N\}$. Since action in stage 1 is private, stages 1 and 2 are considered strategically simultaneous. The (deterministic) information revelation protocol is now formally introduced as a function $R : M^2 \times \Theta^2 \rightarrow \Theta \cup \phi$, which has the following form

\[
R(P, P, \theta) = R(N, N, \theta) = \phi
\]

\[
R(P, N, \theta) = \theta_1 \quad \text{and} \quad R(N, P, \theta) = \theta_2
\]

where $\phi$ stands for the null set.

In stage 3, the voter observes $R(M, \theta) = \rho \in \Theta \cup \phi$ and votes for either candidate, and the utilities are realized. Assume that if the winning candidate’s type is $\theta$, the voter receives a utility of $\theta$. The voter’s action is $v_i(\rho)$, which is the probability of voting for candidate $i$. Assuming that the voter votes for both candidates with the same probability whenever he is indifferent, we have $v_i(\rho) \in \{0, \frac{1}{2}, 1\}$. The utility of candidate $i$ from debate is $u_i(M, \theta) = 2 \cdot v_i(\rho)$, $i = 1, 2$. The total utility of the candidate, as before, is the utility from winning the debate less the search cost $c \in (0, \frac{1}{2})$. Our equilibrium concept is symmetric Bayesian Nash equilibrium.

7.1 Voter and candidate strategies

In the game $G$, the voter rationally forms beliefs about candidate types based on information $\rho$ and $M$. However, the structure of the game is such that the only thing that matters for ranking the candidates is $\rho$ and not $M$. Suppose the expected type of candidate $i$ is $\mu(\theta_i|\rho)$. Since this is also the expected utility from a candidate when he is elected, the voter compares $\mu(\theta_1|\rho)$ and $\mu(\theta_2|\rho)$ and votes for whichever is higher. If they are equal, the voter randomizes with equal probability.

If $\rho = \phi$, both candidates are playing the same action. Since the candidates are playing symmetric strategies, the voter cannot distinguish between the two. Hence, $\mu(\theta_1|\phi) = \mu(\theta_2|\phi)$, and therefore $v_i(\phi) = \frac{1}{2}$. If $\rho = \theta_i$, the type of candidate $i$ is known to be $\theta_i$ while $\mu(\theta_{-i}|\theta_i)$ is inferred by the voter either by Bayes Rule from equilibrium strategies or by out-of-equilibrium beliefs. Hence, the called rational voting strategies are:

\[
v_i(\theta_i) = \begin{cases} 
1 & \text{if } \theta_i > \mu(\theta_{-i}|\theta_i) \\
0 & \text{if } \theta_i < \mu(\theta_{-i}|\theta_i) \\
\frac{1}{2} & \text{if } \theta_i = \mu(\theta_{-i}|\theta_i)
\end{cases} \quad (4) \\
v_i(\phi) = \frac{1}{2}
\]

The strategy space is defined by the functions $p(\theta)$, $q(\theta)$ and $r(\theta, \theta')$ as mentioned in section 3. Note that this set-up can handle any type space of reasonable generality. First, consider a binary type space.
### 7.2 Binary Type space

Suppose that there are only two types: Good ($G$) and Bad ($B$). In formal terms, $\Theta = \{G, B\}$, where $G$ and $B$ are two real numbers with $G > B$. The distribution $F(\cdot)$ now becomes Bernoulli, with the prior $\Pr(\theta_i = G) = \alpha \in (0, 1)$ for $i = 1, 2$. It is shown here that for a natural specification of out-of-equilibrium beliefs, the game $\mathcal{G}(\{G, B\}, \alpha, c)$ has the same unique symmetric equilibrium as the game $\mathcal{H}(\alpha, c)$ discussed in the main body of the paper\(^\dagger\). To demonstrate that, we show that for game $\mathcal{G}(\{G, B\}, \alpha, c)$, rational voting strategy is the same as passive voting strategy considered in $\mathcal{H}$, and therefore leads to the same outcome. Define passive voting strategy as

$$v_i(\rho) = \begin{cases} 1 & \text{if } \rho = \theta_i = G \\ 0 & \text{if } \rho = \theta_i = B \\ \frac{1}{2} & \text{if } \rho = \phi \end{cases}$$

Assume that if $\theta_i \in \{G, B\}$ is revealed out of equilibrium in a debate, then the voter assumes that both types $G$ and $B$ of candidate $-i$ have small positive probabilities $\eta_G$ and $\eta_B$ of having deviated and played $N$. This implies that off the equilibrium path,

$$B < \mu(\theta_{-i}|\theta_i) < G, \quad \theta_i \in \{G, B\}$$

Next, note that in game $\mathcal{H}$, for action profiles that constitute the equilibrium, whenever any type $\theta$ of candidate $i$ is revealed, there is a positive probability of both types $G$ and $B$ of candidate $-i$ to have attacked candidate $i$. Hence, along the equilibrium path too, by Bayes rule, we must have condition (5) satisfied. The next Lemma established this fact more generally for the game $\mathcal{G}(\{G, B\}, \alpha, c)$:

**Lemma 2** In the game $\mathcal{G}(\{G, B\}, \alpha, c)$, there is no symmetric equilibrium where for some type $\theta_i \in \{G, B\}$, we have $\mu(\theta_{-i}|\theta_i) = \theta_i$.

**Proof.** In Appendix B. ■

From Lemma 2, we have for any equilibrium strategy profile of the game $\mathcal{G}(\{G, B\}, \alpha, c)$

$$B < \mu(\theta_{-i}|\theta_i) < G, \quad \theta_i \in \{G, B\}$$

(6)

Conditions (5) and (6) imply that if $\Theta = \{G, B\}$, we must have

$$\mu(\theta_{-i}|\theta_i) > \theta_i \text{ if } \theta_i = B$$

$$\mu(\theta_{-i}|\theta_i) < \theta_i \text{ if } \theta_i = G$$

\(^\dagger\)To be exact, these games are specified differently, so the equilibria can never be the same. What we mean is that in equilibrium, the candidate and voter behaviour are the same in both games.
From (4), the rational voting strategy supporting any equilibrium of $G$, on and off the equilibrium path, is:

$$v_i(\rho) = \begin{cases} 
1 & \text{if } \rho = \theta_i = G \\
0 & \text{if } \rho = \theta_i = B \\
\frac{1}{2} & \text{if } \rho = \phi 
\end{cases}$$

Hence, passive voting is rational here. Therefore, we have the following proposition:

**Proposition 4** Given the out-of-equilibrium beliefs stated in (5), the solution to $G(\{G,B\}, \alpha, c)$ is the same as the solution to the game $H(\alpha, c)$.

### 7.3 Continuous Type Space

This section demonstrates that all the results proved in the case of the binary type space extend naturally to a case where quality can vary over a continuum. Moreover, the continuum breaks into a "good" set and a "bad" set endogenously.

Normalize the type space $\Theta$ and consider it to be the unit interval $[0,1]$. Suppose $F(\cdot)$ is a non-atomic prior distribution from which $\theta$ is drawn. Assume that $F(\cdot)$ has full support over $\Theta$. Note that voter inference in this case is non-trivial. If some candidate is revealed to be of type $\theta \in (0,1)$, then the attacker potentially can be of a type that is strictly better, equal or strictly worse. In the two-type model, both types were extreme - and therefore revelation of one type was enough for the voter to decide. What is interesting is that in the continuous model too, there is a class of equilibria in which rational voting looks very much like passive voting.

The strategy functions $p(\theta), q(\theta)$ and $r(\theta, \theta')$ are defined in the same way as in Section 3, except that these are functions over $[0,1]$ - assume them to be continuous except at a finite number of points.

Next, define $h(\theta, \theta')$ as the probability of the event that conditional on candidates of types $\theta$ and $\theta'$ respectively, the one with type $\theta$ employs campaign $P$. This is the equivalent of $\theta P \theta'$ as defined in (1) in the discrete set-up. Formally,

$$h(\theta, \theta') = (1 - p(\theta))q(\theta) + p(\theta)r(\theta, \theta'), \text{ where } \theta, \theta' \in [0,1]^2 \quad (7)$$

Using (7), define $g(\theta, \theta')$ as the probability that type $\theta$ is revealed through a fruitful debate against type $\theta'$. In other words, $g(\theta, \theta')$ is the probability of the event that conditional on type $\theta$ facing type $\theta'$, type $\theta$ uses $P$ and type $\theta'$ uses $N$.

$$g(\theta, \theta') = h(\theta, \theta') (1 - h(\theta, \theta')) , \text{ where } \theta, \theta' \in [0,1]^2 \quad (8)$$

Next, define $e(\theta)$ as the expected type of candidate $-i$ when candidate $i$ has been revealed to be of type $\theta$. Formally, $e(\theta) = \mu(\theta_{-i} | \theta_i = \theta)$. When a type $\theta$ is revealed in equilibrium with positive
probability, using (8), \(e(\theta)\) can be calculated as:

\[
e(\theta) = \frac{\int_{\theta'}^{1} g(\theta, \theta') dF(\theta')}{\int_{0}^{1} g(\theta, \theta') dF(\theta')}, \quad \text{when} \quad \int_{0}^{1} g(\theta, \theta') dF(\theta') > 0 \tag{9}
\]

If some type \(\theta\) is not revealed in equilibrium with a positive probability, then \(e(\theta)\) has to be determined by an appropriate specification of out of equilibrium beliefs.

Signaling games with continuous types often admit multiple equilibria. Both Banks (1990) and Callander and Wilkie (2005) use the refinement of universal divinity to select equilibria. Here, the main interest is in the link between passive and rational beliefs, and specifically in the existence of equilibria that can be supported by passive beliefs. To avoid equilibria that are too dependent on beliefs off the equilibrium path, assume the following restriction on the set of equilibria:

In equilibrium, all types \(\theta \in \Theta\) should be revealed with positive probability, i.e.

\[
\int_{0}^{1} g(\theta, \theta') dF(\theta') > 0 \quad \text{for all} \quad \theta \in \Theta \tag{10}
\]

This guarantees that \(e(\theta)\) is defined by (9) for all \(\theta\).

Given any symmetric strategy profile \(p(\theta), q(\theta)\) and \(r(\theta, \theta')\), separate the type space into disjoint sets \(G, \widetilde{M}\) and \(B\) such that

\[
G = \{\theta : e(\theta) < \theta\} \\
B = \{\theta : e(\theta) > \theta\} \\
M = \{\theta : e(\theta) = \theta\}
\]

If in a fruitful debate, a type is revealed to belong to \(G\) (\(B\)), then the rival is strictly worse (better) in expectation. Therefore, given any symmetric strategy profile, any equilibrium of the continuous type game will be of the following kind: the type space will be partitioned into sets \(G, B\) and \(M\) such that in a fruitful debate, a candidate revealed to be in \(G\) wins and a candidate revealed to be in \(B\) loses. Since we are looking for equilibria that are similar to those in the two-type case, consider equilibria where \(\widetilde{M}\) is a collection of a finite number of points, and thus has measure zero. Hence, our next restriction on the set of equilibria is

\[
\Pr(\theta : e(\theta) = \theta) = 0 \tag{11}
\]

Hence, if there is an equilibrium of the continuous type game with restriction (11), it would look like the equilibrium with binary types and passive strategies.

To put more structure on the set of equilibria, consider another restriction. This restriction
is not necessary for the existence of binary equilibria with passive voting strategies. However, it selects equilibria among those with such strategies that lead to a “natural” interpretation of good and bad. This is a weaker form of the monotonicity restriction in PY.\textsuperscript{16} Define the expected utility in equilibrium for type $\theta$ of player $i$ as $U_i(\theta)$, and stipulate that in equilibrium a type must not have a strictly greater expected utility than a higher type, i.e.

$$\text{For } \theta, \theta' \in \Theta^2, \theta < \theta' \Rightarrow U_i(\theta) \leq U_i(\theta') \quad (12)$$

Proposition 5 is a formal statement of the existence and characterization of equilibria in the continuous type case satisfying the above restrictions. It demonstrates that the type space endogenously breaks into two sets which conform to the “natural” definition of good and bad, and that the equilibrium with the binary type space is replicated. There is a cut-off type above which all types are deemed to be “good” and below which all types are deemed to be “bad”. Note however that this cutoff type is not unique. In fact, any threshold in the range $(F^{-1}(c), F^{-1}(1 - c))$ can serve as the cut-off type. Thus, it is possible that in two electorates where the prior distributions from which the two candidates are drawn are exactly the same, the definition of a good candidate and a bad candidate are different. Comparative static conclusions are difficult to draw because of the multiplicity of equilibria, but it can be said that the supportable set of cut-off types expands as the search cost decreases.

**Proposition 5** Consider any $\theta^*$ such that $c < F(\theta^*) < 1 - c$, and define sets $G = \{\theta : \theta > \theta^*\}$ and $B = \{\theta : \theta < \theta^*\}$. Then the following is an equilibrium obeying restrictions (10), (11) and (12):

$$p(\theta) = \begin{cases} p(G) & \text{if } \theta \in G \\ p(B) & \text{if } \theta \in B \end{cases}$$

$$q(\theta) = \begin{cases} q(G) & \text{if } \theta \in G \\ q(B) & \text{if } \theta \in B \end{cases}$$

$$r(\theta, \theta') = \begin{cases} 1 & \text{if } \theta \in G, \theta' \in G \\ r(G) & \text{if } \theta \in G, \theta' \in B \\ r(B) & \text{if } \theta \in B, \theta' \in G \\ 0 & \text{if } \theta \in B, \theta' \in B \end{cases}$$

where, if $\alpha = 1 - F(\theta^*)$, the quantities $p(G)$, $p(B)$, $q(G)$, $q(B)$, $r(G)$ and $r(B)$ are given by Proposition 1 part (ii). Moreover, no other symmetric equilibrium satisfies all the three restrictions (10), (11) and (12).

**Proof.** Suppose first voters behave passively by voting in favor of a candidate revealed to be of type greater than $\theta^*$, against a candidate revealed to be of type less than $\theta^*$ and with probability $\frac{1}{2}$

\textsuperscript{16}Polborn and Yi (2006) assumes that expected utility strictly increases in type - here weak monotonicity is assumed.
for each candidate when neither’s type is revealed. Then, from the point of view of the candidates, we have the same game as we would have in the two-type case, with all types in $G = \{ \theta : \theta > \theta^* \}$ behaving like type $G$ and all types in $B = \{ \theta : \theta < \theta^* \}$ behaving like type $B$. Since the probability of a candidate’s type being in $G$ is $1 - F(\theta^*) = \alpha \in (c, 1 - c)$, the unique equilibrium candidate behavior given passive voting strategy is going to be the same as is described by Proposition 1 part $(ii)$.

To see that passive voting is rational, notice that in the said equilibrium of the two-type case, there is fruitful debate only between different types. Therefore, if a type is revealed to be $\theta > \theta^*$, i.e., $\theta \in G$, the rival’s type must satisfy $\theta \in B$, i.e., $\theta < \theta^*$. Clearly, if $\theta \in G$, then the expected type of the rival is $e(\theta) = E(\theta|\theta \in B) < \theta^* < \theta$. Similarly, if a type is revealed to be $\theta \in B$, then the expected type of the rival is $e(\theta) = E(\theta|\theta \in G) > \theta^* > \theta$. Therefore, passive voting is indeed rational in equilibrium.

It is easy to see that all types are revealed with positive probability and $Pr(\theta \in M) = Pr(\theta = \theta^*) = 0$. Thus, restrictions (10) and (11) are satisfied. Moreover, notice that if there is any equilibrium satisfying these two restrictions, it must be the case that all types in $G$ should get strictly higher expected utility than all types in $B$. Moreover, two types in $G$ (and two types in $B$) should get equal expected utility. The only way to satisfy restriction (??) then is to have a cut-off equilibrium where all types above a threshold belong to $G$ and all types below a threshold belong to $B$. In other words, the above class of equilibria is the only class among symmetric equilibria that satisfies all three restrictions. ■

8 Appendix B: Proofs Omitted from the Main Text

To define the equilibrium strategies in this setting, some basic notation needs to be introduced.

Define $Eu^\theta_i(M|p, q, r, I)$ as the expected utility from debate to type $\theta \in \{ G, B \}$ of player $i$ and from playing message $M \in \{ P, N \}$ when player $-i$ is using strategies $p(\cdot), q(\cdot)$ and $r(\cdot, \cdot)$, and the information available to player $i$ is $I \in \{ G, B, \phi \}$. If there is search and the type of the rival ($\theta_{-i}$) is known by $i$ then $I = G$ or $I = B$, else, $I = \phi$. This expected utility is constructed from the debate payoff $u_i(M, \theta)$, taking expectation over the possible messages of the rival $-i$ and if the rival type is not known, then over possible types of the rival too.

Define as $Eu^\theta_i(m|p, q, r, I)$ the expected utility when type $\theta$ of player $i$ plays message $P$ with a probability $m \in [0, 1]$. $Eu^\theta_i(m|p, q, r, I)$

Define $EU^\theta_i(S|p, q, r) = E_{(\theta')} \left[ \arg \max_{m \in [0, 1]} Eu^\theta_i(m|p, q, r, \theta') \right] - c$ as the expected utility from search, taking into account the optimal message choice post search, and taking expectation over rival types and $EU^\theta_i(NS, m|p, q, r) = Eu^\theta_i(m|p, q, r, \phi)$ as the expected utility from not searching and playing a mix $m$ of messages.

Equilibrium strategies is a triad of functions $\{ p^*(\cdot), q^*(\cdot), r^*(\cdot, \cdot) \}$ for $\theta \in \{ G, B \}$ and $\theta' \in \{ G, B \}$. 
Suppose not. Hence,
Proof. Claim 2 he knows that the rival is of type
different from action in the message space, i.e.

For Proof. Using claim
Equilibrium strategies for different parameter values.

When a candidate of type \( \theta \) knows that his rival is also of type \( \theta \), then the candidate has a strictly dominant message. Denote this message by \( D(\theta) \). Denote by \( \overline{D(\theta)} \) the other available action in the message space, i.e. \( \overline{D(\theta)} = \{P, N\} \setminus D(\theta) \). In the same way, denote by \( \overline{\theta} \) the type different from \( \theta \), i.e. \( \overline{\theta} = \{G, B\} \setminus \theta \).

We shall first prove a few results in the form of claims and use those results to find the equilibrium strategies for different parameter values.

Claim 1 \( \text{Eu}_i^\theta (D(\theta)|p, q, r, \theta) - \text{Eu}_i^\theta (\overline{D(\theta)}|p, q, r, \theta) = 1 \)

Proof. For \( \theta = G \), \( D(\theta) = P \), and \( \overline{D(\theta)} = N \)
\[
\text{Eu}_i^G(P|p, q, r, G) - \text{Eu}_i^G(N|p, q, r, G) = \{GPG_{-i} + 2(1 - GPG_{-i})\} - \{(1 - GPG_{-i})\} = 1 \\
\]
For \( \theta = B \), \( D(\theta) = N \), and \( \overline{D(\theta)} = P \)
\[
\text{Eu}_i^B(N|p, q, r, B) - \text{Eu}_i^B(P|p, q, r, B) = \{(1 - BPB_{-i}) + 2BPB_{-i}\} - \{BPB_{-i}\} = 1 \\
\]
The above claim establishes that if type \( \theta \) finds it strictly dominant to use message \( D(\theta) \) when he knows that the rival is of type \( \theta \).

Claim 2 If \( p_i(\theta) > 0 \), we must have \( \text{Eu}_i^\theta (D(\theta)|p, q, r, \overline{\theta}) < \text{Eu}_i^\theta (\overline{D(\theta)}|p, q, r, \overline{\theta}) \)

Proof. Suppose not. Hence, \( \text{Eu}_i^\theta (D(\theta)|p, q, r, \overline{\theta}) \geq \text{Eu}_i^\theta (\overline{D(\theta)}|p, q, r, \overline{\theta}) \).

Since \( p_i(\theta) > 0 \), we must have
\[
\text{Eu}_i^\theta (S|p, q, r) \geq \max \left[ \text{Eu}_i^\theta (NS, P|p, q, r), \text{Eu}_i^\theta (NS, N|p, q, r) \right]
\]
Using claim 1, we can rewrite this as
\[
\text{Pr}(\theta)\text{Eu}_i^\theta (D(\theta)|p, q, r, \theta) + \text{Pr}(\overline{\theta}) \max \left[ \text{Eu}_i^\theta (D(\theta)|p, q, r, \overline{\theta}), \text{Eu}_i^\theta (\overline{D(\theta)}|p, q, r, \overline{\theta}) \right] - c \\
> \max \left[ \text{Eu}_i^\theta (NS, D(\theta)|p, q, r), \text{Eu}_i^\theta (NS, \overline{D(\theta)}|p, q, r) \right]
\]
From our supposition,
\[
\text{LHS} = \text{Pr}(\theta)\text{Eu}_i^\theta (D(\theta)|p, q, r, \theta) + \text{Pr}(\overline{\theta})\text{Eu}_i^\theta (D(\theta)|p, q, r, \overline{\theta}) - c \\
= \text{Eu}_i^\theta (NS, D(\theta)|p, q, r) - c
\]
Now, $RHS = \max \left\{ \Pr(\theta)EU_i^\theta(D(\theta)|p, q, r, \theta) + \Pr(\bar{\theta})EU_i^\theta(D(\theta)|p, q, r, \bar{\theta}), \right. \\
\left. \Pr(\theta)EU_i^\theta(D(\theta)|p, q, r, \theta) + \Pr(\bar{\theta})EU_i^\theta(D(\theta)|p, q, r, \bar{\theta}) \right\}$

By claim 1 and our supposition, $RHS = EU_i^\theta(NS, D(\theta)|p, q, r) > EU_i^\theta(NS, D(\theta)|p, q, r) - c = LHS$, which is a contradiction. ■

The above claim establishes that whenever there is search with a positive probability, type $\theta$ uses message $D(\theta)$ when he knows that the rival is of type $\bar{\theta}$. Claims 1 and 2 determine what actions will be played by a type when the rival type is known. Note that the choice of message post search is independent of the strategy of the rival type. Thus,

$$EU_i^\theta(S|p, q, r) = \Pr(\theta)EU_i^\theta(D(\theta)|p, q, r, \theta) + \Pr(\bar{\theta})EU_i^\theta(D(\theta)|p, q, r, \bar{\theta}) - c$$

(13)

Claim 3 $EU_i^\theta(S|p, q, r) - EU_i^\theta(NS, D(\theta)|p, q, r) = \Pr(\theta) - c$

Proof. By equation (13), $EU_i^\theta(S|p, q, r) - EU_i^\theta(NS, D(\theta)|p, q, r)$ equals

$$\Pr(\theta) \left[ EU_i^\theta(D(\theta)|p, q, r, \theta) - EU_i^\theta(D(\theta)|p, q, r, \theta) \right] + \Pr(\bar{\theta}) \left[ EU_i^\theta(D(\theta)|p, q, r, \bar{\theta}) - EU_i^\theta(D(\theta)|p, q, r, \bar{\theta}) \right] - c$$

By claim 1, the above expression equals $\Pr(\theta) - c$ ■

Note that $c = \alpha$ or $c = 1 - \alpha$ are not considered in our range of parameter values. Thus, between and no search with $D(\theta)$, one always strictly dominates the other, based on the values of the parameter. Most importantly, if type $\theta$ searches with positive probability, he will not play the message $D(\theta)$ conditional on not searching. If the probability of search is strictly between 0 and 1, then $D(\theta)$ will be played by $\theta$ conditional on playing action $X = NS$.

Claim 4 $EU_i^\theta(S|p, q, r) - EU_i^\theta(NS, D(\theta)|p, q, r) = \Pr(\bar{\theta})(2\theta P_{-i} - 1) - c$

Proof. By equation (13), $EU_i^\theta(S|p, q, r) - EU_i^\theta(NS, D(\theta)|p, q, r)$ equals:

$$\Pr(\theta) \left[ EU_i^\theta(D(\theta)|p, q, r, \theta) - EU_i^\theta(D(\theta)|p, q, r, \theta) \right] + \Pr(\bar{\theta}) \left[ EU_i^\theta(D(\theta)|p, q, r, \bar{\theta}) - EU_i^\theta(D(\theta)|p, q, r, \bar{\theta}) \right] - c$$

By simple algebra, the above expression equals $\Pr(\bar{\theta})(2\theta P_{-i} - 1) - c$. ■

This claim, along with claim 3, establishes that when there is search by type $\theta$ of player $i$, we must have $\Pr(\bar{\theta})(2\theta P_{-i} - 1) - c \geq 0$. If there is indifference between search and no search, then the inequality must be satisfied as an equality. Note that this depends on the strategy of the rival candidate.
8.1 Proof of Lemma 1

When the rival is known to be bad, the expected payoff of type \( G \) from using \( P \) is \( BPG + 2(1 - BPG) - c \), and that from using message \( N \) is \( 2BPG + (1 - BPG) - c \). Thus, the net gain from using \( P \) instead of \( N \) is \( (1 - 2BPG) - c \); and that from using message \( N \) is \( 2BPG + (1 - BPG) \). Thus, the net gain from using \( P \) instead of \( N \) is \( (1 - 2BPG) - c \); which is strictly positive if \( BPG < \frac{1}{2} \) and negative if \( BPG > \frac{1}{2} \). This proves the first part of (a). When the rival is unknown, the payoff to type \( G \) from message \( P \) is \( f_G \) and that from playing \( N \) is \( f_G + (1 - f_G) \). The gain from playing \( P \) instead of \( N \) is \( 1 - 2BPG \); which is strictly positive if \( BPG < \frac{1}{2} \) and negative if \( BPG > \frac{1}{2} \). This proves the second part of (a).

With the four basic claims and Lemma 1, we can find the equilibrium, i.e. prove proposition 1.

8.2 Proof of proposition 1

Part (i): \( \alpha < c \)

By claim 4, \( \alpha < c \) \( \Rightarrow \) \( \text{EU}^B_i(S[p,q,r]) < \text{EU}^B_i(NS,N[p,q,r]) \)

By claim 3, \( 1 - \alpha > c \) \( \Rightarrow \) \( \text{EU}^B_i(S[p,q,r]) > \text{EU}^B_i(NS,P[p,q,r]) \)

Thus, for type \( B \) of either player, using the negative message and not searching strictly dominates other strategies.

Hence, \( p(B) = q(B) = 0 \) \( \Rightarrow \) \( BPG = 0 \). By Lemma 1 part (a), \( q(G) = r(G) = 1 \), also, \( BPG = 0 \) implies

\[ \text{EU}^G_i(S[p,q,r]) - \text{EU}^G_i(NS,P[p,q,r]) = -c < 0 \Rightarrow p(G) = 0. \]

Part (iii): \( \alpha > 1 - c \)

By claim 4, \( 1 - \alpha < c \) \( \Rightarrow \) \( \text{EU}^G_i(S[p,q,r]) < \text{EU}^G_i(NS,P[p,q,r]) \)

By claim 3, \( \alpha > c \) \( \Rightarrow \) \( \text{EU}^G_i(S[p,q,r]) > \text{EU}^G_i(NS,N[p,q,r]) \)

Thus, for type \( G \) of either player, using the positive message while not searching strictly dominates other strategies.

Hence, \( p(G) = 0 \) and \( q(G) = 1 \) \( \Rightarrow \) \( GPB = 1 \). By Lemma 1 part (b), \( q(B) = r(B) = 1 \), by claim 2, \( r(B) = 1 \) \( \Rightarrow \) \( p(B) = 0 \)

Part (ii): \( c < \alpha < 1 - c \)

Here, \( \min(\alpha, 1 - \alpha) > c \). Therefore, by claim 3, for \( \theta \in \{G, B\} \),

\[ \text{EU}^\theta_i(S[p,q,r]) - \text{EU}^\theta_i(NS,D(\theta)[p,q,r]) > 0. \]

Thus, whenever the action \( NS \) is played by type \( \theta \) with positive probability, \( D(\theta) \) is the message employed, or

\[ p(G) < 1 \Rightarrow q(G) = 1 \text{ and } p(B) < 1 \Rightarrow q(B) = 0 \]

Next, we claim that we cannot have search with certainty for either type.
Claim 5 We cannot have \( p(\theta) = 1 \) in equilibrium for \( \theta \in \{G, B\} \).

Proof. It has already been established that \( p(\theta) = 0 \) in equilibrium for \( \theta \in \{G, B\} \) as long as \( \alpha < c \) or \( \alpha > 1 - c \). We need to prove this claim only for the case \( c < \alpha < 1 - c \). Suppose \( c < \alpha < 1 - c \) and \( p(G) = 1 \) for \( i \). Therefore, \( GPB_i = r(G) \), and by Claim 2, \( r(G) = 0 \). This implies by 1 part (b) that for \(-i\), \( r(B) = q(B) = 0 \Rightarrow BPG_{-i} = 0 \) (by Lemma 1). Using this in claim 3, we have a contradiction, since

\[
EU_i^G(S|p, q, r) - EU_i^G(NS, P|p, q, r) = -c < 0 \Rightarrow p(G) = 0.
\]

Now, suppose \( c < \alpha < 1 - c \) and \( p(B) = 1 \) for \( i \). Therefore, \( BPG_i = r(B) = 1 \). Using this in claim 3, we have a contradiction, since

\[
EU_i^G(S|p, q, r) - EU_i^G(NS, P|p, q, r) = (1 - \alpha) - c > 0 \Rightarrow p(G) = 1
\]

and we have just shown that we cannot have \( p(G) = 1 \) in equilibrium. ■

Equation (14) and claim 5 together establish that in equilibrium with \( c < \alpha < 1 - c \), we must have \( q(G) = 1 \) and \( q(B) = 0 \). Using this in claim 4 and Lemma 1 part (b), we can show similarly that neither type will have \( p(\theta) = 0 \). Therefore, we must have \( p(\theta) \in (0, 1) \) for both types and for both players. By claim 2, \( r(B) = 1 \) and \( r(G) = 0 \).

Also, from claim 4, we must have for indifference between search and no search for type \( \theta \),

\[
Pr(\bar{\theta})(2\bar{\theta}P\theta - 1) = c \Rightarrow \bar{\theta}P\theta = \frac{1}{2} \left( 1 + \frac{c}{Pr(\bar{\theta})} \right)
\]

Since \( BPG = p(B) \) and \( GPB = 1 - p(G) \), we are done.

8.3 Proof of Lemma 2

Suppose the assertion is false, and we have \( \mu(\theta_{-i}|\theta_i = G) = G \). This must be on the equilibrium path due to assumption (5) on off-equilibrium beliefs. Note that \( v_i(G) = \frac{1}{2} \). This implies that irrespective of the message profile, whenever two good types meet, they both get a debate utility of 1. This implies that \( X = S \) is strictly dominated. To see that, suppose the good type of a candidate plays a mix \( m_B \) of messages against the bad type and \( m_G \) of messages against the good type conditional on search. Since any strategy against the good type of the rival fetches a payoff of 1, the candidate can be better off (by an amount \( c \)) by not searching and employing a mix \( m_B \).

Now, for \( \mu(\theta_{-i}|\theta_i = G) = G \) to be true we need the good type to have fruitful debate with good type with positive probability, i.e. \( GPG \in (0, 1) \) and type \( B \) never to reveal type \( G \), which happens when either \( BPG = 1 \) or \( GPB = 0 \).

Since \( p(G) = 0 \), \( GPG = GPB = q(G) \). If \( GPG > 0 \), we can rule out \( GPB = 0 \).
If $BPG = 1$, we must have $q(G) = 0$, i.e. $GPG = 0$, which is a contradiction.

Thus, it is established that we cannot have $\mu(\theta_G|\theta_i = G) = G$ in equilibrium. In the same fashion, we can show that we cannot have $\mu(\theta_B|\theta_i = B) = B$ in any equilibrium with rational voting.

### 8.4 Proof of Proposition 3

The proof of this proposition is exactly similar to that of proposition 1, except that the relevant expressions are different. Hence we only provide the sketch of the proof.

The result equivalent to Lemma 1 is as follows

**Lemma 3 (1.1)** For $\theta \in \{G, B\}$, the message choice by type $\theta$ conditional on not searching (i.e. $q_\theta$), and the message choice conditional on searching and finding the rival type to be different (i.e. $r_\theta$), is given by:

(a) On finding the rival to be a bad type, the good type uses a positive message ($r_G = 1$) or a negative message ($r_G = 0$) depending on

$$BPG \leq \frac{b - a_2}{2b - (a_1 + a_2)}$$

Conditional on not searching, the good type employs a positive message ($q_G = 1$) or a negative message ($q_G = 0$) depending on

$$BPG \leq \frac{b - a_2 + \Pr(G)\pi}{2b - (a_1 + a_2)}$$

(b) On finding the rival to be a good type, the bad type uses a positive message ($r_B = 1$) or a negative message ($r_B = 0$) depending on

$$GPB \geq \frac{b - a_2}{2b - (a_1 + a_2)}$$

. Conditional on not searching, the bad type employs a positive message ($q_B = 1$) or a negative message ($q_B = 0$) depending on

$$GPB \geq \frac{b - a_2 + \Pr(B)\pi}{2b - (a_1 + a_2)}.$$

The generalized results corresponding to the four claims are as follows

**Claim 6** $Eu_i^\theta(D(\theta)|p, q, r, \theta) - Eu_i^\theta(\overline{D(\theta)}|p, q, r, \theta) = \pi > 0$
Claim 7 If \( p_i(\theta) > 0 \), we must have \( EU_i^p(D(\theta)|p,q,r,\theta) < EU_i^p(D(\theta)|p,q,r) \)

Claim 8 \( EU_i^q(S|p,q,r) - EU_i^q(NS,D(\theta)|p,q,r) = \phi \Pr(\theta) - c \)

Claim 9 \( EU_i^q(S|p,q,r) - EU_i^q(NS,D(\theta)|p,q,r) = \Pr(\theta)[(\overline{\theta}P\theta-(2b - (a_1 + a_2)) - (b-a_2)] - c \)

As corollary to claim 9, we have

\[
\alpha < \frac{c}{b-a_1} \Rightarrow EU_i^G(S|p,q,r) < EU_i^G(NS,N|p,q,r) \quad (15)
\]

\[
1 - \alpha < \frac{c}{b-a_1} \Rightarrow EU_i^G(S|p,q,r) < EU_i^G(NS,N|p,q,r) \quad (16)
\]

Proof of part (i) of proposition: \( \alpha < \frac{c}{b-a_1} \) and \( \alpha < \frac{1}{2} \)

By equation (15), \( EU_i^G(S|p,q,r) < EU_i^G(NS,N|p,q,r) \). Since \( \pi \geq b-a_1 \), we have \( \frac{c}{\pi} \leq \frac{c}{b-a_1} < \frac{1}{2} \). By claim 8, \( EU_i^G(S|p,q,r) > EU_i^G(NS,N|p,q,r) \). Therefore, \( p_B = q_B = 0 \Rightarrow BPG = 0 \Rightarrow q_G = r_G = 1 \) (By Lemma 3). Also, \( BPG = 0 \Rightarrow p_G = 0 \) by claim 9.

Proof of part (ii) of proposition: \( \alpha > 1 - \frac{c}{b-a_1} \) and \( \alpha > \frac{1}{2} \)

By equation (16), \( EU_i^G(S|p,q,r) < EU_i^G(NS,N|p,q,r) \). Since \( \pi \geq b-a_1 \), we have \( 1 - \alpha < \frac{1}{2} < 1 - \frac{c}{b-a_1} \leq 1 - \frac{c}{\pi} \Rightarrow \alpha > \frac{c}{\pi} \). By claim 8, \( EU_i^G(S|p,q,r) > EU_i^G(NS,N|p,q,r) \). Therefore, \( p_G = 0, q_G = 1 \Rightarrow GPB = 1 \Rightarrow r_B = 1 \) (By Lemma 3). By Lemma 3, we also have \( q_B = 1 \) only if

\[
2b - (a_1 + a_2) \geq \frac{1-\alpha}{\alpha} \pi + (b-a_2), \text{i.e. \( \alpha \geq \frac{\pi}{(b-a_1)+\pi} \). Now, \( c < \frac{(b-a_1)^2}{(b-a_1)+\pi} \Rightarrow 1 - \frac{c}{b-a_1} > 1 - \frac{b-a_2}{(b-a_1)+\pi} \). Therefore, \( \alpha > 1 - \frac{c}{b-a_1} \Rightarrow q_B = 1 \)
\]

Proof of part (ii) of proposition: \( \alpha > 1 - \frac{c}{b-a_1} \)

Since \( b-a_1 \leq \pi \), we have \( \alpha > \frac{c}{b-a_1} \geq \frac{c}{\pi} \). By claim 8, \( EU_i^G(S|p,q,r) > EU_i^G(NS,N|p,q,r) \). Therefore, \( p_G < 1 \Rightarrow q_G = 1 \). Again, \( \alpha < 1 - \frac{c}{b-a_1} \leq 1 - \frac{c}{\pi} \Rightarrow 1 - \alpha > \frac{c}{\pi} \). By claim 8, \( EU_i^G(S|p,q,r) > EU_i^G(NS,N|p,q,r) \). Therefore, \( p_B < 1 \Rightarrow q_B = 0 \).

The following claim establishes uniqueness of the equilibrium.

Claim 10 There is no equilibrium with (i) \( p_\theta = 1 \) for \( \theta \in \{G,B\} \).

Proof. Already shown for \( \alpha > 1 - \frac{c}{b-a_1} \) and \( \alpha < \frac{c}{b-a_1} \). Now, consider the case with \( \frac{c}{b-a_1} < \alpha < 1 - \frac{c}{b-a_1} \). Suppose \( p_G = 1 \) for some \( i \). Then \( GPB_i = r_G \). Also, \( r_G = 0 \) by Claim 7. By Lemma 3, \( r_B = q_B = 0 \Rightarrow BPG_i = 0 \). By Claim 8, \( EU_i^G(S|p,q,r) < EU_i^G(NS,N|p,q,r) \). Therefore, \( p_G = 0 \) by Claim 7, \( BPG_i = r_B = 1 \). By Claim 9, \( EU_i^G(S|p,q,r) = EU_i^G(NS, S|p,q,r) = (1-\alpha)(b-a_1) - c > 0 \), since \( \alpha < 1 - \frac{c}{b-a_1} \). Thus, \( p_G = 1 \), which cannot occur in equilibrium, as we just saw before. ■

Claim 10 implies that \( q_G = 1 \) and \( q_B = 0 \) whenever \( \frac{c}{b-a_1} < \alpha < 1 - \frac{c}{b-a_1} \). Similarly, we can show that we cannot have \( \overline{\theta} = 0 \) in equilibrium for \( \theta \in \{G,B\} \) whenever \( \frac{c}{b-a_1} < \alpha < 1 - \frac{c}{b-a_1} \). Therefore, for this range of \( \alpha \), we must have \( p_\theta \in (0,1) \). Also, from claim 7, \( BPG = p_B \) and \( GPB = 1 - p_G \).
